Chelating agents must be pH adjusted by using acids or alkalis, depending on the type of chelating agent and the scale constituents to be complexed. For example, under alkaline conditions, the sodium salt of EDTA will complex calcium-containing deposits, but it will not remove iron oxide.

In boiler cleaning, the most common chelating agent is the ammonium salt of EDTA, which is used to remove Fe_3O_4 scale from boilers at 75 to 150 °C (170 to 300 °F). Following this, the solution is oxidized using oxygen gas or hydrogen peroxide to remove copper. This solution must be inhibited to prevent corrosion of the steel.

Some chelating processes are patented, and some have expired patents, such as the Alkaline Copper Removal Process (Dow) which uses tetraammonium EDTA at a pH of 9.0 to 9.5 for removing copper and iron oxides from a boiler

while it is intermittently fired. Another chelating agent is the CitroSolv Process, which uses inhibited ammoniated citric acid to dissolve iron oxides and sometimes copper in utility steam generators (patent for Pfizer, also expired.) Chelating agents can often be incinerated, minimizing disposal problems.

Copper complexers such as thiourea are added to HCl when both iron and copper oxide deposits are present. The complexers help dissolve the copper and prevent it from plating out on steel in the system.

Chromic acid has been used at 7 to 10%, primarily to remove iron pyrite and certain carbonaceous deposits that are insoluble in HCl. The iron pyrite is oxidized to the sulfate without the evolution of H_2S . With carbonaceous deposits, H_2CrO_4 degrades the tar that holds the deposits together. The use of H_2CrO_4 in industrial cleaning has become rare due to environmental and safety concerns.

Chromic acid is a strong oxidizing agent and should not be used on copper, brass, bronze, aluminum, zinc, or cast iron. It is acceptable on carbon steel and stainless steel. Steel piping should be used for handling it because non-metallic hose materials, other than PTFE, are rapidly degraded.

Caustic plus permanganate is widely employed as a pretreatment in refinery-cleaning operations to remove carbonaceous deposits coupled with pyrophoric sulfides. A solution of 1% NaOH and 0.7% $KMnO_4$ is used at 65 to 80 °C (150 to 175 °F). This converts iron sulfide to iron oxide and sulfate, both of which can be removed with acid cleaning. Little or no H_2S is generated. If HCl is used for the acid-cleaning step, oxalic acid should be added to reduce any chlorine gas that might be evolved upon reaction with the insoluble manganese dioxide formed during the first stage of cleaning.

Organic solvents used to dissolve organic deposits include kerosene, xylene, toluene, xylene bottoms, heavy aromatic naphtha, 1,1,1-trichloroethane, *N*-methyl-2-pyrrolidone, alcohols, glycols, and ortho-dichlorobenzene (Ref 3, 4).

Although very effective in cleaning, the chlorinated solvents have fallen into disuse in recent years due to safety and environmental concerns. In the United States, some solvents are strictly regulated by the Environmental Protection Agency (EPA), Occupational Safety and Health Administration (OSHA), and state and local regulations. The use of any solvents should be carefully reviewed. With few exceptions, rubber hoses or rubber-lined equipment should not be used to handle organic solvents.

Organic emulsions are solvent-based cleaners for heavy organic deposits, such as tar, resid (residual oils), asphalts, and polymers. A typical formulation would consist of an aromatic solvent and emulsifying agents. The mixture should be capable of being heated to 65 to 82 °C (150 to 180 °F). A thorough rinsing step is necessary to remove the sludge left behind when the cleaning

agent is drained. Proprietary emulsion solvent blends are also sometimes used.

Passivating solutions are used to prevent carbon steel from rusting after acid cleaning, before it is returned to service. The term passivation is also applied to procedures that are used to remove surface iron contamination from stainless steel and titanium equipment. Most passivating solutions for carbon steel are alkaline and contain an oxidizing agent, even if it is only air. They are applied after rinsing and neutralization.

For the passivation of austenitic stainless steel and welding slag removal, 20% HNO_3 plus 2% HF is commonly used at 50 °C (120 °F) for 6 h. The actual necessary parameters depend on the specific alloy. Titanium can be passivated with nitric acid, but HF should not be used on this metal.

Corrosion inhibitors are added to chemical cleaning agents to permit effective cleaning without excessive corrosion of the equipment. Most inhibitor formulations are organic compounds and function in three ways (Table 2):

- Cathodic inhibitors impede the cathodic half of the corrosion reaction, for example, $2H^+ + 2e^- \rightarrow H_2$.
- Anodic inhibitors limit the anodic half of the corrosion reaction, for example, $Fe \rightarrow Fe^{2+} + 2e^-$.
- Adsorption inhibitors form a physical barrier on the metal surface and prevent corrosion.

Inhibitors must be capable of dispersing or dissolving in the chemical cleaning solution, both fresh and contaminated. They must also be compatible with the equipment materials of construction; for example, low-chloride inhibitors should be used on stainless steels.

The concentration of the inhibitor used is related to the type of solvent, its temperature, the equipment materials of construction, the surface-to-volume ratio in the equipment, and the degree of turbulence. Typical film-forming inhibitor concentrations for mineral acids on steel are of the order of 0.2% (V), more or less.

Most common inhibitors are proprietary formulations, and technical data may be obtained from suppliers. Various inhibitors sometimes contain dyes, which confirm whether or not the inhibitor has been added.

Chemical Cleaning Procedures

The choice of cleaning method, selection of the cleaning solution, and monitoring and documentation requirements should be included in a proposed procedure. Selection of the chemical cleaning contractor is important because the quality of individual crews can vary. Also, the contractor must have the ability and experience to use specific procedures, some of which may require unique steps or patented procedures. The proposed procedure should be written and included in a scope of work that is mutually

agreeable to the owner and the contractor. During the project, the key elements must be documented.

Solvent Selection

Proper selection of the solvent system for a chemical cleaning project requires laboratory analysis of a recent sample of the deposit.

Sampling. Great care should be exercised in taking the sample and in shipping it properly, since the analysis is essential to the proper selection of a solvent. For a boiler, the best sample is a tube cut from the water wall at an area that historically had the heaviest deposit, usually the high heat flux area of the boiler. Deposit samples chipped from the metal may suffice in place of a tube cut if no tube section is available and if all deposit layers are included in the sample.

All deposit samples should be labeled with clear distinguishing descriptions to prevent confusion. A sample from before the last cleaning or from the most recent opening of the equipment can be submitted for analysis if a current sample cannot be obtained. Historical information from past cleanings is also helpful, but both of these approaches may fail to account for later episodes of process upsets and changes that can cause layers of deposit which may be more difficult to remove. Water samples, and deposit samples taken from filters, provide only limited information about the deposits on heat-exchanger tubes. Such limited information can be misleading and should not be relied upon as the sole basis for solvent selection.

Laboratories usually require minimum sample sizes. A typical minimum size for a loose deposit sample is 30 g (1 oz). When selecting a tube sample, ASTM D 3483 (Ref 5) specifies a minimum tube length of 0.6 m (2 ft) for removal by dry sawing or grinding. For torch-cut tube sections, laboratories need a minimum tube length of 0.9 m (3 ft). The longer length requirement when the tube section is taken using a cutting torch is because the ends are

Table 2 Classification of corrosion inhibitors

Classification	Example
Cathodic	Alkylamines Benzotriazole (L) Diphenylamine Thiourea (L)
Anodic	Benzotriazole (H) Mannich bases Pyridines Quinolines Thiols Thioureas (H)
General adsorption	Acetylenic alcohols Benzotriazole Dibenzylsulfoxide Diphenylamine Furfuraldehyde

L, at low concentration; H, at high concentration

contaminated by slag and will be cut off and discarded by the lab. Boiler tube sections from tubes that failed should not be used since the violence of the tube blowout will have removed some of the deposit. Samples smaller than the minimums can limit the information that the laboratory can produce.

Lab Report. When the samples are sent, a clear understanding should exist about what will be reported. Allow 2 to 4 weeks for normal handling and reporting. At a minimum, the lab report(s) should provide the following information for each sample:

- Chemical composition of the deposit
- Results of solubility tests
- Descriptions of unusual observations or appearances

Chemical composition of the deposit can be determined by several methods. In one method, the sample is digested in a boiling acid. This is usually followed by spectrometer analysis of the solution.

Results of Solubility Tests. Beaker tests are usually sufficient to indicate which solvents will work in cleaning the equipment, and which is best.

Solvent Choice Based on Deposit Type and Metallurgy. Table 1 summarizes the choices of solvents versus deposits commonly found in boilers and versus construction metals.

In addition to selecting the optimum solvent, other factors essential to successful chemical cleaning are the development of a safe and effective procedure and the prevention of excessive equipment corrosion.

Procedural Stages

The scope of the work should be documented and can be organized in stages.

Planning Stage. The proposed cleaning procedure should be reviewed with the contractor or personnel who will conduct the cleaning. The procedure should outline the specific duties of the contractor and the owner and should include:

- Listing of all chemicals and quantities used, including primary solvent and corrosion inhibitor, surfactants, emulsifiers, neutralizers, passivators, and antifoams
- System volume and solution contact times, temperatures, and pressures
- Method of corrosion control and monitoring
- Special contractor equipment required, such as filter elements, high-volume pumps, reversing manifolds, flow meters, and heat exchangers
- Contractor safety procedures and owner safety requirements, for example, methods of treating hazardous by-products, such as hydrogen sulfide (H_2S) and hydrogen cyanide (HCN), which may be generated during cleaning
- Disposal requirements for waste material, including adherence to federal, state, and local regulations

- Lay-up requirements after cleaning, if equipment is not to be used immediately

When mutually agreed upon, the procedure is developed into a scope of work.

Cleaning Stage. The equipment is readied for cleaning. After isolation, all restrictions, such as orifice plates, should be removed. Tubes of a shell and tube heat exchanger should be cleaned of obstructions before chemical cleaning. Failure to free the tubes could result in solvent remaining in tubes and possible damage at start-up. In general, the chemical cleaning operation consists of:

1. Connecting cleaning system
2. Leak testing of the liquid circulation path, including contractor fittings and temporary piping
3. Establishment of circulation rate and temperature
4. Blending in of chemicals
5. Circulation and monitoring, which include recording of solvent strength and deposit removal; if the solvent strength remains constant for three or more consecutive readings, cleaning is usually considered complete
6. Draining system of solvent
7. Flushing with water
8. Neutralizing, if an acidic solvent was used
9. Passivation, if required
10. Inspection and evaluation of cleaning

Documentation of Cleaning. A simple format will include relevant information on the equipment temperature, materials of construction, chemicals, method of circulation, time of circulation, and evaluation of equipment. The format may be modified for different pieces of equipment.

Corrosion Monitoring in Chemical Cleaning. Chemical cleaning introduces the real possibility of equipment damage from corrosion. Various precautions may be taken to eliminate damage or to reduce the corrosion rate to acceptable levels, such as reducing the cleaning temperature or contact time. Corrosion monitoring during chemical cleaning may consist of on-line electrochemical monitoring, corrosion coupons, or a bypass spool piece containing a sample of the deposit.

On-line electrochemical monitoring provides an instant record of the corrosion rate during cleaning. However, localized corrosion effects may not be indicated.

Corrosion coupons are sometimes used. They should be representative of the materials of construction of the equipment being cleaned, and should be insulated from one another to avoid galvanic effect. If necessary, special coupons, such as U-bends, should be included to check for SCC. The corrosion rates of coupons are generally higher than the actual corrosion rate of the equipment during the cleaning cycle. However, excessively high coupon rates suggest that cleaning has been performed outside of the desired range of temperature, chemical

concentration, or circulation rate. Experience dictates that acceptable corrosion rates should be obtained from corrosion coupons. Localized corrosion observed on coupons is unacceptable. A bypass spool piece containing a sample of the deposit is the ideal coupon because it will indicate the effectiveness of the cleaning as well as the condition of the metal after cleaning.

The use of corrosion coupons during chemical cleaning is not recommended, as they may provide inaccurate results because:

- In the early part of the chemical cleaning circulation, the deposit protects the equipment, while the clean metal coupon is exposed to both ferric ion corrosion and acid corrosion. Ferric ion corrosion is rapid, and the coupon can suffer accelerated corrosion during this period
- Sometimes it is not possible or practical to place the coupons in the equipment being cleaned. Corrosion coupons placed in the cleaning contractor's equipment suffer higher corrosion due to high flow rates and turbulence

Postinspection is extremely important to check for damage and to gage the effectiveness of cleaning. Certain scales may increase the corrosiveness of the chemical cleaning solution as they dissolve.

Corrosion Rate. Chemical cleaning contractors measure the general corrosion rate in pounds per square foot per day ($lb/ft^2 \cdot d$). This unit is converted to mils per year (mils/yr) by using a factor that varies with the density of the metal under consideration. To obtain mils per year, multiply pounds per square foot per day by $70.3 \times 10^3 / \text{density}$ (grams per cubic centimeter). For steel, $0.01 lb/ft^2/d = 91 \text{ mils/yr}$. Further corrosion rate conversion information is found in Reference Information in this Volume.

A significantly higher corrosion rate is tolerable during chemical cleaning than would be allowed in service. For example, 400 mils/yr obtained from coupons may be acceptable for carbon steel. With relatively thick components, such as pump casings, even higher rates may be tolerable. Less than 200 mils/yr should be the goal. Localized forms of corrosion, for example pitting or SCC, are not tolerable.

Localized Corrosion. The principal forms of localized corrosion that occur during chemical cleaning are pitting, SCC, and under-deposit corrosion (crevice corrosion).

Pitting occurs when filming inhibitors break down or there is insufficient inhibitor addition. Pitting will also occur with HCl and incompatible metals, such as aluminum or stainless steels. Oxidizing conditions, such as free Fe^{3+} ion, and the presence of the chloride ion (Cl^-) will also encourage pitting in metals resistant to general corrosion, especially the active-passive metals mentioned. Pitting is especially harmful on thin-wall equipment, for example, heat-exchanger tubes.

Stress-corrosion cracking is likely to occur in specific chemical alloy combinations when

the threshold temperature and concentration requirements for cracking are exceeded. This usually occurs in vapor spaces, splash zones, or crevices where the cleaning agent can concentrate. If the chemical cannot be washed out, SCC may occur later, for example, during service. The two most common situations to guard against are the hydroxyl ion (OH^-), for example, from caustic, with carbon steel and the chloride (Cl^-) ion, for example, from HCl, with austenitic stainless steels. In some cases, an inhibitor can be added to minimize cracking. Hydrogen-assisted cracking may also occur in hardenable low-alloy and stainless steels in specific heat treated conditions during acid cleaning.

Cracking of carbon steel (caustic embrittlement) can be inhibited by adding sodium nitrate to the alkaline cleaning solution at a ratio of one part of sodium nitrate per two parts caustic. There is no proven way to inhibit stainless steel from chloride SCC.

Under-deposit corrosion occurs when cleaning is incomplete and the deposits left behind harbor or concentrate corrosives. The corrosion is difficult to see because it is hidden by the deposits.

Temperature, Pressure, and Flow Rate. Of these factors that affect corrosion rate, temperature is the most significant. The higher the temperature of the solvent, the more effective the cleaning generally is. However, corrosion rate increases significantly with temperature and limits the temperature that can be used (Fig. 1). Increasing temperature also increases the amount of inhibitor required.

Each cleaning operation should include a review of the pressure (hydrostatic and gas) that may be experienced. Acceptable limits should not be exceeded. For example, in one operation, impervious graphite heat-exchanger tube failures were significantly reduced when the circulating solvent pressure was decreased from 690 to 207 kPa (100 to 30 psig).

It is extremely difficult to relate flow rate or solution velocity directly to the corrosion rate. This is because the key to increased corrosion

rate is turbulence. Experience is the best indicator of velocity or flow limitations during chemical cleaning.

Ferric ion corrosion is a form of general or localized corrosion that occurs on carbon steel, nickel, Monel 400, copper, brass, and zirconium during chemical cleaning. The effect is worst with HCl (because of the presence of the Cl^- ion), but can also occur in other mineral acids, citric acid, EDTA chelant formulations, and formic acid.

Ferric iron corrosion occurs when there are heavy deposits of rust (hematite) or aeration during cleaning. Dissolution of rust or aeration during cleaning generates the Fe^{3+} ion, which corrodes steel as follows:

Other metals can also be corroded because of the oxidizing nature of the Fe^{3+} ion, especially if the Cl^- ion is present.

Ferric iron corrosion may be prevented with specific inhibitors, for example, stannous chloride (SnCl_2). It prevents the formation of Fe^{3+} ion:

Stannous chloride, though very effective, is rarely used because it introduces a heavy metal into the cleaning waste. The most commonly used ferric iron inhibitor today is erythorbic acid or its less expensive form, sodium salt. Erythorbic acid is the optical isomer of ascorbic acid, which is vitamin C, and it is virtually nontoxic. Proprietary Fe^{3+} ion corrosion inhibitors are also available.

Even if an Fe^{3+} ion inhibitor is added, the total iron content (ferrous and ferric) must be monitored regularly (at least every 30 min) during acid cleaning. Measurement of the Fe^{3+} ion content may be misleading. When the iron content reaches 2 to 3%, the solution should be removed.

Sulfide Corrosion. Sulfides are present in many refinery deposits, and extremely toxic H_2S gas may be released when sulfides are contacted by acid cleaning solutions. Sulfides and H_2S are very corrosive and reduce the effectiveness of corrosion inhibitors. Hydrogen sulfide will also crack hardenable low-alloy steels and blister low-strength carbon steels.

Corrosion problems with sulfides and H_2S may be reduced by lowering the acid concentration and temperature. Inhibitors are effective in preventing cracking or blistering. An aldehyde may be added to the acid cleaning solution to prevent the generation and release of the corrosive and deadly hydrogen sulfide gas. (Ref 6). Glyoxal ($\text{C}_2\text{H}_2\text{O}_2$) is the most commonly used aldehyde in H_2S suppression in chemical cleaning.

Sulfide stringers present in free-machining steels have increased susceptibility toward corrosion during acid cleaning. Selenium-containing free-machining steels or low-sulfur regular grades are less susceptible to attack.

Effectiveness of Corrosion Inhibitor. A useful qualitative test to check whether a filming inhibitor has been added to the system before circulation is the steel wool test. In this test, a small wad of steel wool is completely immersed in a beaker containing the inhibited acid at the strength and temperature to be used during cleaning. If the inhibitor addition is effective, there should be no hydrogen evolution from the beaker for at least 5 min and the wad of steel wool should remain at the bottom of the beaker. Other, more quantitative tests that measure hydrogen generation are also sometimes used.

As noted previously, by-products formed during cleaning can reduce the effectiveness of the corrosion inhibitor. Also, increasing temperature and concentration of cleaning chemicals usually necessitates a greater dose of inhibitor.

"Fish Scaling" of Glass-Lined Equipment. Due to the relatively low heat transfer of glass, the jackets of glass-lined equipment may require frequent cleaning to remove rust, algae, and the like. Hydrochloric acid or any other acid solutions, even if inhibited, should not be used to remove jacket deposits from the jackets of glass-lined equipment. The corrosion rate of the steel jacket is sufficiently high to generate hydrogen. Hydrogen atoms generated by the corrosion reaction diffuse through the steel to the glass/steel interface, where they form hydrogen molecules and accumulate and build up pressure at the glass/steel interface.

The buildup of hydrogen eventually disrupts the bond between the glass and steel and the glass spalls. The initial form of the attack has the appearance of fish scale, but in most cases sufficient hydrogen is generated to result in complete removal glass from a relatively large surface area of the vessel. Reglassing of the entire vessel is then required.

To counter the problem, several proprietary neutral solutions have been developed to remove rust from the jackets of glass-lined vessels. They operate at pH 5 to 7, depending on the formulation, and do not corrode steel. They contain reducing agents, plus a complexing agent, and also surfactants and wetting agents. The reducing agent converts ferric ions in the deposit to ferrous ions, which are then tied up (dissolved) by the complexing agent. Surfactants and wetting agents in the formulations aid dissolution.

For removal of algae alone, a mild solution of sodium hypochlorite may be used.

On-Line Chemical Cleaning

The cleaning methods discussed so far require that the equipment be removed from service and opened to some degree for the cleaning. In some cases, on-line cleaning is effective and more convenient. On-line cleaning can be chemical or mechanical, infrequent or regularly scheduled. Effective on-line cleaning can save time and labor and can prevent a shutdown. Mechanical methods are discussed in a later

LIVE GRAPH
Click here to view

Fig. 1 Effect of temperature on corrosion of mild steel in uninhibited HCl

section. Examples of chemical on-line cleaning include:

- Depressing pH or adding sequestrants and dispersants in a cooling water system
- Increasing chelant or dispersant feed to a boiler
- Injecting inhibited mineral acid into the cooling water stream in front of a heat exchanger for a few minutes and neutralizing it downstream

The first two examples may be executed by a water treatment company. The last example may be executed by a cleaning contractor, but should be coordinated with the water treatment company since it can impact the cooling-water chemistry.

Mechanical Cleaning

Mechanical cleaning is extensively used to clean many types of equipment. There are three broad categories: hydraulic, abrasive, and thermal.

The hydraulic category includes water cleaning, high-pressure water blasting, ultrahigh-pressure water blasting, and ultrasonic cleaning. The abrasive category includes rodding, drilling, sandblasting, pigging and scraping, turbinizing, and explosive removal. The thermal category includes steam cleaning.

Hydraulic cleaning is carried out at pressures from 2070 kPa to 221 MPa (300 to 32,000 psig). Water cleaning is often used to flush mud and debris from pipelines at pressures to 2070 kPa (300 psig). Slug flow flushing with air injection will obtain better scouring and will conserve water. Water, coupled with a pipeline pig, is often effective in removing scale and corrosion products from lines.

High-pressure water cleaning (hydroblasting), the most common form of mechanical cleaning, is carried out at pressures of 6.9 to 69 MPa (1000 to 10,000 psig). It is used to remove such deposits as light rusting, minerals, and polymers. There are three types of high-pressure water cleaning: tube lancing, line mousing, and shotgun jetting.

In tube lancing, a rigid or flexible lance is used to clean the inside of tube bundles, and the operation is repeated for each tube. In line mousing, a short self-propelled jet nozzle (mole) and a high-pressure hose are used to clean the inside of piping. In shotgun jetting, a relatively short handheld gun (shotgun) is used to clean surfaces that cannot be cleaned practically by the other means. Shotgun jetting is not effective in cleaning tubes.

High-pressure water cleaning reduces the risk of corrosion damage to equipment, and disposal of the water is less of a problem than with chemical cleaning. Also, the risk of generating hazardous or toxic by-products is eliminated.

The jetted stream is provided by an operator holding a water lance. The lowest pressure with appropriate volume of water is selected,

consistent with achieving the required degree of cleaning. This is dictated by experience and risk to personnel.

High-pressure water cleaning must be done by trained personnel using appropriate safety devices and regularly inspected equipment. The area around the project should be suitably barricaded and signs posted.

Line friction leads to a significant loss of pump pressure. To counteract friction loss when pumping through a long hose, organic polymers have been developed that, when added to water in concentrations as low as 0.05 to 0.1%, reduce friction loss as much as 90%.

Ultrahigh-pressure water blasting is conducted at 221 MPa (32,000 psig), using a flow rate of 3.8 to 15 L/min (1 to 4 gal/min). The low flow rate means there is a very low back thrust, allowing the equipment to be operated in congested work spaces with a higher degree of safety. The ultrahigh pressure and low volume of delivery are achieved by using intensifiers rather than the standard plunger pumps. Nozzle configurations are tailored to the application. The nozzle is usually held 19 to 100 mm (0.75 to 4 in.) away from the workpiece. The tooling is specially designed for specific applications, primarily scale, rust, and polymer removal; tube bundle cleaning; and such specialized items as cleaning turbines, diaphragms, and rotors. Cleaning is not effective around more than one 90° turn. The low volume of water minimizes disposal problems.

The technique is particularly advantageous where high-pressure water blasting is ineffective and sandblasting is not desirable, for example, adjacent to pumps, valves, and compressors. Ultrahigh-pressure water blasting has been cost effective in preparing surfaces for inspection, such as the wet fluorescent magnetic-particle inspection of welds. In these cases, an inhibitor is added to the water to prevent flash rusting.

Ultrahigh-pressure water blasting is a proprietary process and is limited to a few vendors who tailor their tools to specific projects. It is more expensive than high-pressure water blasting, but has the advantages of quality and speed.

Hydrokinetic cleaning uses high-frequency vibration or cavitation to remove fouling from the inside of pipes and heat-exchanger tubes. Pulsing a pressurized water column against a plug in the pipe creates the vibration and cavitation. The plug is formed by either the fouling material or by inserting a fabricated "bullet" or "pig" inside the pipe. A small amount of air is also inserted with the water stream to create cavitation. Although the bullet will restrict flow and build pressure in the water column, a small amount of the water is intended to bypass the bullet through the annulus between the bullet and the pipe inside diameter. This creates high-velocity flow at the wall of the pipe and is essential to allow flushing of materials ahead of the bullet as well as to keep the bullet moving through the pipe.

Pulsation of the water stream creates vibration that is transmitted through the water column and to the wall of the pipe and fouling material. The pipe and fouling materials are excited at different frequencies because of their difference in densities. These contrasting vibrations break the cohesion between the fouling material and the pipe wall, and the fouling material is flushed out of the pipe by the water stream. Hydrokinetic cleaning is best when the pipe is partially or completely blocked and the material is polymeric, such as polyethylene.

Aqua milling is a rotary mechanical cutting process for removing scale and fouling from tubing and pipe. The pipe may be coiled, straight, or it may have elbows. Aqua milling can clean pipe with diameters from 25 mm to 3 m (1 in. to 10 ft). Vertical and horizontal vessels up to 7.6 m (25 ft) diam may also be cleaned. Deposits vary from surface scale to full blockage. They may be rubbery, plastic, or brittle.

Unlike high-pressure water cleaning, only one access point is required. Aqua milling is a semiautomatic cleaning system that does not require vessel entry or hands-on lancing. Special jets create hammering impact rather than slicing of scale as seen with high-pressure water cleaning. Aqua milling is not a substitute for high-pressure water cleaning, but may be considered when high-pressure water cleaning takes an extremely long time or when it is necessary to remove personnel from the location of the lance, as in a confined space.

Abrasive cleaning is implemented where hydraulic cleaning may not be practical.

Rodding is used for lightly plugged heat-exchanger tubes where scale has not built up. Care should be taken to prevent scoring of the tubes.

Drilling may be used on tightly plugged heat-exchanger tubes. The drill is hollow, and a fluid connection is used to flush out freed material, eliminating the need to pull the drill out to clear the point and remove loose material.

Sandblasting involves cleaning the internal surface of process lines and equipment by using an abrasive-blasting tool. These are available for different pipe sizes. A standard sandblast nozzle is used that impinges the sand against the conical carbide tip of the nozzle, spraying the sand out radially against the walls of the tube. A circular end plate removes most of the sand as the tool is pulled back out of the pipe.

Piping and Scraping. Pipeline pigs and scrapers are sometimes used, alone or with special chemicals, to clean pipelines. This is a combination of mechanical and chemical cleaning. The pig is a flexible bullet-shaped foam cylinder that is propelled through the pipeline with water. A typical system consists of several pigs, launching and trapping facilities, and a water source. Pigging has been used to clean lines from 25 to 914 mm (1 to 36 in.) in diameter.

Turbinizing is a tube- or pipe- cleaning method that uses air, steam, or water to drive a motor that turns cutters, brushes, or knockers in order to remove deposits. Many different heads are

available for different deposits and equipment, including models for curved tubes. Overzealous turbinizing may damage pipes because the cutter types will cut into the base metal. Also, turbinizing is relatively slow and costly compared to other mechanical and chemical methods.

Explosive removal of pipe deposits requires experience and has been used on hard and brittle deposits in piping. Primacord is manufactured in various degrees of explosive power; selection of the proper strength depends on pipe size and type of deposit.

Thermal cleaning is the third major mechanical cleaning method. This method is performed by plant operations personnel. Steam, nitrogen, and oxygen are mixed and injected into the tubing in a furnace section with the fire going for a carefully controlled oxidation of carbon deposits in the tubes.

Steam cleaning can be used to remove mill scale and debris from lines and equipment. When mixed with oxygen, steam cleaning can remove coke and polymers from equipment.

On-Line Mechanical Cleaning

Chemical on-line cleaning was discussed previously. Some examples of mechanical on-line cleaning include:

- Side-stream filtration
- Air bumping of heat exchangers
- Washing soft deposits from steam turbines
- Reversing flow in heat exchangers
- Passing brushes or sponge balls through exchanger tubes

Not all cleaning projects are conducive to on-line cleaning. Hard or insoluble deposits may not be removed effectively. In boilers, if the deposit

is heavy, on-line cleaning may cause the deposit to slough and plug tubes—possibly leading to tube failures. Also, some on-line cleaning costs can be high, for example, the initial cost of installing brushes or sponge balls to clean heat exchangers. Each case must be evaluated individually to determine if on-line cleaning will be cost effective.

Introduction to Corrosion in Specific Industries

Hira S. Ahluwalia, Material Selection Resources Inc.

CORROSION-RELATED DIRECT COSTS, such as prevention methods and infrastructure repair and replacement, make up 3.1% of the U.S. gross domestic product—a value of approximately \$276 billion annually—according to the 2002 study sponsored by the U.S. Federal Highway Administration (FHWA) (Ref 1), with support from NACE International. The study estimates that 25 to 30% of the cost is entirely preventable. The current state of knowledge contained in the *ASM Corrosion Handbooks* provides valuable information that can be applied to reduce the cost of corrosion. The *ASM Handbook Volume 13A, Corrosion: Fundamentals, Testing, and Protection*, 2003, addresses those topics and includes a summary of the FHWA report. The *ASM Handbook Volume 13B, Corrosion: Materials*, 2005, addresses the corrosion resistance of materials of construction and includes the article “Global Cost of Corrosion—A Historical Review.”

This Section, “Corrosion in Specific Industries,” applies the fundamental understanding of corrosion and knowledge of materials of construction to practical applications. The industries addressed are nuclear power, fossil and alternative fuel, land transportation, air transportation, microelectronics, chemical processing, pulp and paper, food and beverage, pharmaceutical and medical technology, petroleum and petrochemical, building, and mining and metal processing. Each specific industry article provides information on the challenges faced in combating corrosion and the appropriate materials of construction and other corrosion control technologies employed to meet these challenges.

Corrosion in the Nuclear Power Industry

The U.S. nuclear industry generates approximately 20% of the electricity needs primarily from reactors designed and built over 30 years ago. Safety concerns continue to plague the industry. Severe cracks found at one nuclear power reactor (ca 2001) and the boric acid corrosion of carbon steel that nearly breached the

152 mm (6 in.) steel dome of another facility (ca 2002) are raising new questions about aging nuclear plants and their inspection methods. By seeking to understand the role of alloys in corrosion, the nuclear industry is in the process of refurbishing and upgrading its facilities in order to extend the design life of plants an additional 20 years. Most nuclear electricity is generated using two types of nuclear reactors that evolved from 1950 designs, namely the boiling water reactor and the pressurized water reactor. The fuel for these types of reactors is similar, consisting of long bundles of 2 to 4% enriched uranium dioxide fuel pellets stacked in zirconium alloy cladding tubes. This Section deals with corrosion issues in light water reactors, research on the corrosion mechanisms, and the development and implementation of engineering solutions.

The burial of spent fuel that has accumulated over the past decades of nuclear power production is another aspect of the industry that has attracted tremendous research and political attention in recent years. Many countries are developing geological repositories for their high-level nuclear waste. These repositories will consist of a stable geological formation within which engineered barriers will be constructed. The engineered barriers are double-walled metallic containers. The article in this Section provides an excellent analysis of the metals and alloys being selected for the metallic cylinders. The corrosion resistance, the effect of metallurgical condition, and the environmental variable that affects the corrosion behavior of the metallic materials are discussed.

Corrosion in Fossil and Alternative Fuel Industries

The three types of fossil fuel power plants primarily used by the electric power industry are coal-fired steam, industrial gas turbine, and combined-cycle power plants. The most common and widely used is the pulverized-coal-fired steam power plant. Because of the complex and corrosive environments in which power plants operate, corrosion has been a serious problem,

with a significant impact on reliability of the plants. This Section deals with corrosion of components that continue to have the greatest effect on the reliability of the power plant. Corrosion of tubular components, for example, in condensers and boilers, appears to be the major challenge. Also discussed in this Section are flue gas systems, especially the wet flue gas desulfurization systems. These are strongly affected by corrosion because of the corrosive nature of flue gas impurities such as sulfur dioxide.

Corrosion in the Land Transportation Industries

This section addresses the automotive industry and also discusses issues related to electric rail corrosion and corrosion in bridges and highways. The automobile industry, for the most part, has become one of the major success stories in corrosion management. The use of electro-galvanized steel, aluminum, and polymers has had a major impact on improving the corrosion performance of automotive bodies. Stainless steel use has increased over the past 25 years. Most exhaust systems use stainless steel or aluminized stainless steel for corrosion resistance.

Corrosion in Commercial Aviation

One of the major concerns of the commercial aircraft and airline industry is the aging of aircraft. The risk and cost of corrosion damage is particularly high in aging aircraft. In April 1988, the sudden decompression of a 19 year old Boeing 737 aircraft and the subsequent separation of a major portion of the upper fuselage resulted in federal airworthiness directives, establishing requirements to prevent or control corrosion in aircraft. The Department of Transportation, Federal Aviation Administration (FAA) Title 14 CFR Parts 121, 129, and 135 require that the maintenance and inspection programs include FAA-approved corrosion prevention and control programs (CPCP). This article describes how the implementation of

CPCP programs has dramatically reduced corrosion damage of aircraft structures. Significant improvements have also been made in the corrosion design and manufacturing of new airplanes. Boeing's newest commercial aircraft, the 787, will use approximately 60% less aluminum and significantly more composite materials and increased amounts of titanium. These more corrosion-resistant materials are expected to significantly reduce maintenance costs.

Corrosion in the Microelectronics Industry

Corrosion in electronic components manifests itself in several ways. Computers, integrated circuits, and microchips are now an integral part of all technology-intensive industry products, ranging from aerospace and automotive to medical equipment and consumer products, and are therefore exposed to a variety of environmental conditions. Corrosion in electronic components is insidious and cannot be readily detected. Therefore, when corrosion failure occurs, it is often dismissed as just a failure, and the part or component is replaced. This Section discusses corrosion in passive electronic and semiconductor integrated circuits and components.

Corrosion in the Chemical Process Industry

Before building a chemical plant, or expanding a current plant, one of the first steps to ensuring safety and reliability is to select proper materials of construction. Understanding the importance of materials selection and making an informed decision is critical in achieving safe and reliable operation of the new facility as well as minimizing the capital cost. This Section deals with corrosion by commercially important acids, bases, and solvents. Each article briefly discusses the various grades, methods of manufacture, their effect on most common metals and plastics, and the most common material of construction used in the manufacture and storage of the acids, bases, and solvents. The cross-industry problem of corrosion under insulation is discussed, with a summary of the corrosion mechanism and effective prevention techniques.

Corrosion in the Pulp and Paper Industry

Corrosion in the pulp and paper industry has been a subject of much discussion and research by the Technical Association of the Pulp and Paper Industry and NACE International. The articles in this Section are a summary of the work done by the NACE International committee. Corrosion, materials of construction, and protection methods used in the principal equipment found in 12 different sections of paper mills are discussed.

Corrosion in the Food and Beverage Industry

The food processing industry is one of the largest manufacturing industries in the United States, accounting for approximately 14% of the total U.S. manufacturing output. Stainless steels and aluminum alloys are the primary materials used in the food and beverage industry. The corrosion environment involves moderately to highly concentrated chlorides, with significant concentrations of organic acids. The water side of the processing equipment can range from steam heating to brine cooling. Chemicals used for clean-in-place procedures pose additional corrosion challenges. This article discusses regulations governing materials and the application of stainless steels in the food industry.

Corrosion in the Pharmaceutical and Medical Technology Industries

According to the 2002 corrosion cost study (Ref 1), the total capital expenditures for the pharmaceutical industry are approximately \$4.5 billion, with up to \$0.5 billion per year in corrosion costs. This figure does not include indirect costs that result because of unexpected loss and downtime of critical equipment and the effect this has on inventories and production scheduling. In the biotechnology sector, the indirect cost can be 10 to 20 times more than the direct cost. The indirect cost is an important consideration when selecting materials of construction for equipment that holds valuable and expensive drugs. Consider a scenario where one batch of final product has to be discarded due to metal-catalyzed damage to the protein. For example, consider a 120 liter final-product vessel constructed of 316 L stainless steel costing \$30,000, or if constructed of a Ni-Cr-Mo alloy such as alloy C-22 costing \$60,000, and holding bulk product worth \$500,000. If one such batch has to be discarded due to the corrosion of 316 L, not only the production cost is lost but the potential revenue and profit. Avoiding the loss of even one single batch easily covers the extra capital expenditure of using more corrosion-resistant materials to ensure no loss of production.

Another incentive to use more corrosion-resistant materials is to ensure compliance to federal regulations, Title 21 CFR Parts 210 and 211, "Current Good Manufacturing Practice in Manufacturing, Processing, Packing, or Holding of Drugs; General and Current Good Manufacturing Practice for Finished Pharmaceuticals." Subpart D-211.65 states "Equipment shall be constructed so that surfaces that contact components, in-process materials, or drug products shall not be reactive, additive, or absorptive so as to alter the safety, identity, strength, quality, or purity of the drug product beyond the official or other established requirements." This regulation clearly states that corrosion of

equipment or product contamination of any kind is not acceptable.

Biomedical prosthetic devices are being increasingly used. Any material placed in the body needs to be compatible and not cause adverse reactions in the body. Corrosion effects on the biocompatibility of metallic materials and implants and the corrosion of biomaterials and dental alloys are also discussed in this Section.

Corrosion in the Petroleum and Petrochemical Industry

A large amount of research and industry standards has been published over the last 15 years. The production of oil and gas, its transportation and refining, and its subsequent use as fuel and raw materials for chemicals is a complex and demanding process, where corrosion is an inherent hazard. This Section discusses corrosion problems and methods of control used in petroleum production, in storage and transportation of oil and gas (including external and internal corrosion of pipelines), and in the refining industry. A useful summary of the industry standards is also presented.

Corrosion in the Building Industries

Carbon steel is the main material of construction used in building construction. This Section discusses carbon steel corrosion in structures and methods used to prevent corrosion of structures.

Corrosion in the Mining and Metal Processing Industries

The mining, mineral processing, and extractive metallurgy industries deal with a wide range of corrosive environments and erosive media. In mining and mineral processing, erosion and erosion-corrosion are the major concerns. Extractive metallurgy often involves the use of aggressive acids and other chemicals. This Section addresses the materials selection challenges faced in this industry.

In conclusion, this Section of the *ASM Handbook* provides excellent practical information that can be applied to reduce the significant cost of corrosion to our society. This important Section would not be possible without the dedication of the knowledgeable subject expert authors who devoted considerable time in the preparation of the articles.

Introduction to Corrosion in the Nuclear Power Industry

Barry M. Gordon, Chair, Structural Integrity Associates, Inc.

THIS SECTION reviews the series of serious corrosion problems that have plagued the light water reactors (LWRs) industry for decades, the complex corrosion mechanisms involved, and the development of practical engineering solutions for their mitigation. However, to understand the nature of LWR corrosion problems, a brief historical perspective of the corrosion design basis of commercial LWRs, that is, boiling water reactors (BWRs) and pressurized water reactors (PWRs), is necessary.

Although corrosion was considered in all plant designs, corrosion was not considered as a serious problem. The major concern was general corrosion, and it was well known at the time of LWR design and construction that the primary structural materials used in the fabrication of the nuclear steam supply system—stainless steels and nickel-base alloys—were characterized by very high general corrosion resistance in high-purity, high-temperature LWR-type environments. The problem was that the “qualifying” laboratory tests did not necessarily reproduce the reactor operating conditions (especially the high residual tensile stresses), and the test times were of short duration relative to the initial plant design lifetime of 40 years, which is currently being extended to 60 years. For example, the initiation time for primary water stress-corrosion cracking (PWSCC) of nickel-base alloys in PWRs can be as long as 25 years! Also, while it was well documented at the time that the presence of chloride in the coolant could cause chloride stress-corrosion cracking (SCC) of stainless steel, there was little evidence that only 0.2 ppm of dissolved oxygen in the highest-purity water could provide the electrochemical driving force for intergranular stress-corrosion cracking (IGSCC) of weld-sensitized austenitic stainless steel.

The initial operation of the early commercial LWRs encountered few corrosion problems. Any problems were quickly repaired and did not have a major impact on plant availability. As more plants entered service and more operating time was accumulated on existing plants, more corrosion-related incidents appeared in the

pipings, reactor internal components, and other components. Eventually, the corrosion of the plant and fuel materials did seriously impact plant availability, economics, reliability, and, in some cases, plant safety. Table 1 presents a brief summary of the corrosion history of LWRs.

To quantify the fiscal impact of these types of corrosion incidents on the cost of operating nuclear power plants, the Federal Highway Administration, Office of Infrastructure Research and Development, funded an economic evaluation (Ref 1) of the cost of corrosion across segments of industry. Also see the article “Direct Costs of Corrosion in the United States” in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A, *ASM Handbook*, 2003. The annual nuclear power costs of corrosion were divided into three main categories:

- Corrosion-related causes of partial LWR outages: \$5 million/year
- Corrosion-related causes of zero power LWR outages: \$665 million/year

- Contribution of corrosion to LWR operation and maintenance (O&M): \$2 billion/year

As can be seen in Table 2, which presents the ten most expensive O&M costs of corrosion for one particular reactor site, Oconee units 1, 2, and 3 PWRs, the cost of corrosion in the nuclear power industry is extremely high. Obviously, this type of cost analysis does not include human “costs” for the loss of life, such as occurred in December 1986 and August 2004 at the Surry 2 and Mihama 3 PWRs, respectively, where a total of 9 workers were killed and 10 others were severely injured due to the rupture of a carbon steel piping due to flow-accelerated corrosion in the two plants.

As indicated in Table 1, the major corrosion-related problems addressed by the reactor operators and owners, the Electric Power Research Institute (EPRI), and the nuclear steam system suppliers include the IGSCC of welded austenitic stainless steel pipes in BWRs, PWSCC of nickel-base alloys and steam

Table 1 A brief summary of the corrosion history of light water reactors

Corrosion event(a)	Time of detection
Alloy 600 IGSCC in a laboratory study	Late 1950s
IGSCC/IASCC BWR stainless steel fuel cladding	Late 1950s and early 1960s
BWR IGSCC of type 304 stainless steel during construction	Late 1960s
IGSCC of furnace-sensitized type 304 during BWR operation	Late 1960s
IGSCC in U-bend region of PWR steam generator	Early 1970s
Denting of PWR alloy 600 steam generator tubing	Mid-1970s
PWSCC of PWR alloy 600 steam generator tubing	Mid-1970s
Pellet-cladding interaction failures of BWR zircaloy fuel cladding	Mid-1970s
IGSCC of BWR welded small-diameter type 304 piping	Mid-1970s
IGSCC of BWR large-diameter type 304 piping	Late 1970s
IGSCC of BWR alloy X-750 jet pump beams	Late 1970s
IGSCC of BWR alloy 182/600 in nozzles	Late 1970s
Accelerating occurrence of IGSCC/IASCC of BWR internals	Late 1970s
PWSCC in PWR pressurizer heater sleeves	Early 1980s
Crevice-induced IGSCC of type 304L/316L in BWRs	Mid-1980s
FAC of single-phase carbon steel systems in PWRs	Mid-1980s
PWSCC in PWR pressurizer instrument nozzles	Late 1980s
IGSCC of BWR low-carbon (304L/316L) and stabilized stainless steels (347/321/348) in vessel locations	Late 1980s–present
IGSCC of BWR internal core spray piping	1980s–present
Axial PWSCC of alloy 600 of PWR top head penetration	Early 1990s
Circumferential PWSCC of J-groove welds	Early 1990s
PWSCC of PWR hot leg nozzle alloy 182/82	Early 2000s
PWSCC-induced severe boric acid corrosion of a PWR head	Early 2000s

(a) IGSCC, intergranular stress-corrosion cracking; IASCC, irradiation-assisted stress-corrosion cracking; BWR, boiling water reactor; PWR, pressurized water reactor; PWSCC, primary water stress-corrosion cracking; FAC, flow-accelerated corrosion

Table 2 Ten most expensive operation and maintenance costs of corrosion for the Oconee units 1, 2, and 3 pressurized water reactors

Work activities	Cost	Cost, %	% attributed to corrosion	Cost of corrosion
Steam generators	\$22,757,765	8.26	95	\$21,619,877
Maintenance engineering support	\$13,204,783	4.79	33	\$4,357,578

Corrosion in Boiling Water Reactors

F. Peter Ford, General Electric Global Research Center (Retired)

Barry M. Gordon, Structural Integrity Associates, Inc.

Ronald M. Horn, General Electric Nuclear Energy

ENVIRONMENTALLY ASSISTED CRACKING (EAC) of structural materials in the boiling water reactor (BWR) reactor pressure vessel (RPV), core internals, and ancillary piping is the focus of this article. The content is substantially different from that in *Corrosion*, Vol 13, *ASM Handbook* (formerly 9th ed., *Metals Handbook*) published in 1987 to reflect technology advances in the intervening 19 years and their relevance to regulatory requirements and business needs. For instance, this article covers effects of water chemistry on materials degradation, new mitigation approaches and their impact on aging-management programs, plus a discussion of life-prediction capabilities that are having an impact on proactive management of BWR materials degradation.

Boiling water reactor topics dealing with localized corrosion of zirconium alloy fuel cladding, plus a detailed analysis of the effects of irradiation on corrosion are addressed in other articles in this Section, "Corrosion in the Nuclear Power Industry." The corrosion of balance-of-plant structures (e.g., condensers, steam turbines, feedwater heaters, etc.) is covered in the Section "Corrosion in Fossil and Alternative Fuel Industries."

Background to Problem

Most currently operating BWRs are direct-cycle systems. That is, water boils in traversing the fuel channels in the core, with the resultant steam containing approximately 10% moisture above the liquid at the top of the core. This moisture content is reduced to less than 0.1% by steam separators and driers in the top head of the reactor vessel; the steam then leaves the pressure vessel at about 7 MPa (1000 psig) and 288 °C (550 °F) to the steam turbine. Upon exiting the turbine, the steam is condensed and the water purified in demineralizers; this water is then reheated in heat exchangers to approximately 225 °C (435 °F) before returning to the reactor. Although earlier reactor designs relied on natural circulation to transport the water coolant around the reactor internals, the majority of currently operating designs rely on external recirculation

pumps and internal jet pumps to control coolant transport and heat transfer within the core. There are differences in specific design details between the various BWR reactor manufacturers (General Electric, ABB-W, KWU-Siemens, Hitachi, and Toshiba), but this general design description is sufficient for the purpose of discussing corrosion issues.

The nuclear steam supply system (NSSS) is very complicated with additional piping associated with, for instance, reactor water cleanup (RWCU), shutdown cooling (SDC), and/or residual heat removal (RHR); these systems ensure core control during normal full-power and transient conditions such as reactor startup and shutdown. A series of emergency core cooling systems (ECCS) ensure core cooling in the event of loss of coolant accidents (LOCA) of varying magnitudes; such piping systems include, for instance, the high- and low-pressure coolant injection (HPCI, LPCI), high- and low-pressure core spray (HPCS, LPCS), and the automatic depressurization system (ADS), which permits effective operation of the low-pressure emergency coolant systems. Although the reliability of these piping systems is critical to the safety of the reactor, there are no corrosion phenomena unique to them and that are not discussed elsewhere in this Volume; thus, for simplicity, discussion of corrosion issues in BWRs is confined to the reactor pressure vessel, its internals, and the external recirculation piping.

Emphasis is placed on materials degradation due to EAC under various combinations of materials, environmental, and stressing conditions. Under static loading conditions EAC is subcategorized as "stress-corrosion cracking" (SCC), or "irradiation-assisted stress-corrosion cracking" (IASCC) for specific irradiated core conditions, and under monotonically increasing strain conditions (for instance, during reactor startup) as "strain-induced corrosion cracking." The detrimental effect of the environment on "dry fatigue" cracking under cyclic loading is subcategorized as "corrosion fatigue." It is important to recognize that these various EAC definitions generally refer to a common environmental degradation process where the stressing mode is changing the kinetics of crack initiation and propagation and, sometimes, the intergranular or transgranular morphology of cracking; the following discussion emphasizes this commonality rather than focusing on the categorizations.

Environmentally assisted cracking has been observed in various BWR structural components over the last 40+ years (Table 1) due to the interactions of specific material, environment, and stress conditions. These occurrences have been described in, for example, the proceedings of a series of biannual symposia and conferences held since 1983 (Ref 1–11), at Electric Power Research Institute (EPRI) sponsored workshops on the development of mitigation approaches

Table 1 Evolution of EAC incidents in boiling water reactors

Component and mode of failure	Alloy	Time period
Fuel cladding, irradiation-assisted SCC	304	1960s
Furnace-sensitized safe ends, IGSCC	304, 182, 600	↓
Weld-sensitized small diameter piping, IGSCC	304	
Weld-sensitized large diameter piping, IGSCC	304	
Furnace-sensitized weldments and safe ends, IGSCC	182/600	
Low-alloy steel nozzles, thermally induced vibration	A508	1980s
Crevice-induced cracking	304L/316L	↓
Jet pump beams, IGSCC	X750	
Cold work induced IGSCC of "resistant" alloys	304L	
Low-alloy steel pressure vessel, TGSCC	A533B/A508	
Irradiated core internals, IASCC	304, 316	↓
IGSCC/IASCC of low-carbon and stabilized stainless steels	304L, 316L, 321, 347	

SCC, stress-corrosion cracking; IGSCC, intergranular stress-corrosion cracking; TGSCC, transgranular stress-corrosion cracking; IASCC, irradiation-assisted stress-corrosion cracking

(Ref 12, 13) and water chemistry issues (Ref 14), and in information notices published on the U.S. Nuclear Regulatory Commission (USNRC) website (Ref 15).

The earliest incidents of EAC in BWRs occurred during the 1960s and were associated with cracking of type 304 stainless steel fuel cladding (Ref 16); the driving forces for the cracking were the tensile hoop stress in the cladding due to the swelling fuel and the highly oxidizing conditions in the water of the core environment. This problem was effectively mitigated when zirconium alloys were substituted for this component, although, as pointed out in other articles in this Section, other modes of corrosion degradation associated with zirconium alloys became apparent. The earliest indications of cracking in austenitic stainless steel piping were associated with transgranular stress-corrosion cracking (TGSCC) due to chloride contamination encountered either during fabrication or operation (Ref 17); this was again exacerbated by the oxidizing conditions in the water and was effectively managed by appropriate control of the chloride contamination. Subsequently, EAC incidents in BWR subsystems have been dominated by intergranular cracking, and, in some cases, these have been detected after relatively short operating times. For instance, such cracking was observed in late 1965 due to intergranular stress-corrosion cracking (IGSCC) in the weld heat-affected zone (HAZ) of a 150 mm (6 in.) type 304 stainless steel recirculation bypass piping after 68 months of plant operation; this cracking morphology was associated with the thermomechanical fabrication conditions that gave rise to a compositional heterogeneity in the grain boundary (which is discussed later). Subsequently, in 1966 and 1967, there were a number of additional pipe-cracking indications found by ultrasonic examination or by leakage. Numerous indications of IGSCC of welded type 304 stainless steel occurred in the fall of 1974 and early 1975; 64 incidents of cracking were identified during this short period, and all of them occurred in small-diameter lines less than 250 mm (10 in.) (Ref 18). During 1978, incidents of IGSCC were first noticed in a large-diameter (610 mm, or 24 in.) pipe in an overseas BWR (Ref 19). This incident posed additional concern because replacement of such large-diameter lines would be difficult, costly, and would require additional leak-before-break and degraded pipe behavior analysis. In 1982, extensive IGSCC of 710 mm (28 in.) recirculation piping was found in a U.S. BWR, and additional inspections revealed cracking in large-diameter piping of other U.S. BWRs (Ref 20, 21). Since the 1980s, other incidents of IGSCC or interdendritic stress-corrosion cracking (IDSCC) have been observed in nickel-base alloys (alloys 600, 182, and X-750) in, for instance, welded safe ends, access hole covers, shroud head bolts, and jet pump beams, as well as TGSCC in limited regions of stainless steels that had been cold worked (Ref 22–24) by, for instance, severe surface grinding. During this period, the impor-

tance of water purity control became increasingly obvious, especially with regard to creviced components where the geometry and oxidizing conditions in the bulk environment could give rise to increased anionic activity in the creviced region (Ref 25, 26) even though the bulk water purity was acceptable at that time. As is discussed later, mitigation of these issues relied on a combination of materials, stress, and environmental modifications, such as the use of lower-carbon (L-grade) stainless steels, which decreased the amount of grain-boundary sensitization and control of the water purity.

Since the mid-1980s, there have been increasing observations of IGSCC in stainless steel core components that have been exposed to neutron irradiation (>1 MeV) beyond a critical fluence level ($>5 \times 10^{20}$ n/cm²) and that were highly stressed. Initially, these incidents were confined to easily replaced components (e.g., in-core instrumentation tubes) but, more recently, IASCC has been observed at lower fluence levels in larger welded core structures, with the extent of cracking depending on the specific combinations of prior thermal-sensitization due to the initial fabrication procedure, fast neutron flux and fluence, weld residual stress, and coolant purity (Ref 27–30). Thus it is apparent that the initial hypothesis that there is a critical “threshold fluence” required for IASCC depending on whether the component is at “high” or “low” stress is probably in error; this point is discussed later in this article. Although the substitution of type 304 stainless steels with L-grade alloys in these irradiated components has increased the operating time before cracking is observed, incidents can still occur (Ref 31), especially if the component has been severely surface cold worked by grinding, straightening, and so forth during manufacture.

Failure of the ferritic carbon steel and low-alloy steel components (e.g., feedwater piping and unclad regions of the pressure vessel) by EAC in BWRs has been very infrequent compared to the incidence rate observed in the austenitic alloys discussed previously. As is discussed later, there are fundamental reasons why it is remarkably hard to sustain crack propagation in the carbon steel and low-alloy steel/BWR environment systems under good water

chemistry and nondynamic loading conditions. The isolated incidents that have been reported have been associated with dynamic loading during plant startup or relatively low-frequency cyclic loading due, for instance, to thermal stratification in piping or inadequate mixing of “hot” and “cold” coolant streams (Ref 32, 33). The morphology of this cracking is generally transgranular, although in a very few isolated incidents the cracking morphology may be intergranular depending on the stressing mode or environmental conditions.

These observations highlight the fact that obvious remedial actions, such as controlling the material sensitivity to grain-boundary compositional heterogeneity (by, for instance, using low-carbon or stabilized stainless steels) to reduce the likelihood of IGSCC, or by improving the water chemistry specifications (by, for instance, controlling the chloride concentration) may not be sufficient for extended operating times. Secondary factors such as surface cold work, radiation effects, or the presence of crevices may well reduce the effectiveness of these “obvious” remedial actions. Thus, long-term management of the materials degradation modes associated with EAC depends on a quantitative understanding of the secondary, as well as primary, interactions among the material, stress, and environmental factors.

Such cracking incidents can be disruptive from an operational viewpoint; for instance, capacity loss due to pipe cracking alone in U.S. BWRs peaked at 16.94% in 1984 before pipe-cracking mitigation actions were widely applied (Ref 34). These incidents are extremely costly in terms of component replacement, lost power availability, and manpower irradiation exposure (Table 2); thus the business driver for the reactor operator and reactor designer to minimize these occurrences and to institute permanent mitigation actions is high. From a regulatory viewpoint there is a requirement that the reactors be periodically inspected and evaluated for continued structural integrity (defined in terms of the risk of structural failure and, ultimately, core damage, and/or unacceptable coolant leakage) during the next operational period before reinspection (normally a fuel reload cycle of 12 to 24 months). These regulatory aspects take on increasing

Table 2 Cost (in millions of U.S. dollars) of repair of boiling water reactor components

Component	Estimated repair cost, \$MM	Radiation exposure, man-rem	Repair time, critical path days	Total cost(a), million USD
Shroud support to vessel weld	250	5500	364	487
Control rod drive stub tube to vessel weld	50	700	225	170
In-core housing	50	225	100	102
Recirculation piping	20	1200	125	95
Recirculation inlet and outlet nozzles	25	300	44	50
Jet pump riser brace	10	26	63	42
Core support plate	4	30	50	29
Top guide	8	15	30	23
Instrumentation penetrations	6	200	25	20
Shroud	4	10	12	10
Manway cover (access hole)	2	5	10	7

(a) Assumptions in calculating total cost: (1) Radiation exposure cost; \$10K/man-rem, (2) Critical path outage cost; \$0.5MM/day, (3) No account taken for “present value analyses.” Source: Ref 34

importance as reactor operators in the United States submit license renewal applications to the USNRC to extend the license period from the current 40 years to 60 years. In addition, BWR operators in the United States are now applying to the USNRC for power uprates of up to approximately 20% over the original licensed rating; such increases are accomplished by core redesign and increased coolant flow, thereby raising questions of increased risk of IASCC of austenitic stainless steels, flow-assisted corrosion (FAC) of carbon steels, and (corrosion) fatigue of some components due to flow-induced vibrations. Given the past BWR materials degradation history, there is the expectation from the regulator that the reactor operator (of both BWRs and pressurized water reactors, PWRs) has in place aging-management programs to address the current and future potential degradation modes in his specific plant. Many of these aging-management programs rely on past operating experience, laboratory studies, and analyses by the utilities (e.g., EPRI), reactor manufacturers, national laboratories, and the technical societies who issue USNRC-endorsed manufacturing and inspection codes (e.g., American Society of Mechanical Engineers, ASME). Examples of such aging-management programs relevant to specific components are described in more detail in Ref 35.

To satisfy the safety-driven expectations of the regulator and the business needs of the reactor operator it is necessary to (a) develop inspection techniques that can, with reasonable probability, detect and adequately size defects in sometimes complex geometries under potentially hazardous (e.g., irradiated) conditions, (b) develop algorithms that predict the kinetics of degradation, with defined degrees of uncertainty, in order to either specify the required inspection periodicity, or to define the amount of damage that might occur in a predetermined inspection interval, and, finally, (c) develop cost-effective mitigation actions that will prevent or mitigate the materials degradation.

The interaction between these requirements is shown schematically in Fig. 1. In this illustration it is assumed that a crack was not detected at inspection 1; that is, the crack depth or length is below the nondestructive examination (NDE) resolution limit, and the question is "Can it be expected that a crack will be detected at the planned inspection 2, and if it is, will the crack dimensions be within acceptable values vis-à-vis safety or leakage?" The quantification of the "acceptable value" will depend on either the dimensions of the component (e.g., pipe) to give leakage, or appropriate "margins of safety" on crack dimensions before unstable crack propagation can occur. If the answer to this preliminary question is uncertain then "Can the reactor continue to be operated if a specific mitigation action is introduced at some intermediate time?" It is important to predict and define these events since significant damage can occur relatively quickly under specific operating conditions, especially if the detection techniques

have limited resolution. For instance, in 1982 through-wall cracking and leakage was observed in recirculation safe-ends at a domestic plant during a hydrostatic test at a position where nine months previously no cracking had been detected (Ref 20).

While the question of detecting and sizing the defect is beyond the scope of this article, attention is focused on the prediction of the cracking kinetics in BWRs and the methods for quantitatively predicting and mitigating materials degradation.

EAC Analysis

Analysis of EAC phenomena in BWRs since the early 1980s has occurred in two phases. The first and crucial one was to quantify the prime physical parameters that control the cracking process; this was necessary in order to define the mitigation actions. The extent of this understanding developed in the 1970s and early 1980s (Ref 12–14, 17, 18) was not enough, however, to answer the detailed life-management questions posed in Fig. 1. These questions could be answered only with a more quantitative understanding of the relationship between cracking susceptibility and the primary and secondary interactions that occur between the various mechanical, environmental, and material parameters controlling the cracking kinetics. This further understanding was developed in the second phase. The following discussion is organized chronologically to mirror this analysis and life-prediction development.

Historically, EAC has been divided into the "initiation" and "propagation" periods. To a large extent this division is arbitrary since, in most engineering situations, "initiation" is defined as the time at which a crack is detected, or when the load has relaxed a specific amount (in, for instance, a strain-controlled test). In both cases, such a definition of initiation corresponds to a crack depth of significant metallurgical dimensions. For instance, detection limits for cracks on the inside surface of a pipe may well be 10% of the pipe wall thickness, that is, approximately 2 mm (80 mils.) if the detection sensor is on the outside surface of the pipe. Similar crack

Fig. 1 Evolution of a crack, and the roles of crack dimension resolution and inspection periodicity in managing the structural degradation

depths correspond to a definition of "initiation" based on a defined amount of load relaxation (say 25%) in a strain-controlled test (upon which current fatigue design codes are based). Thus, for the current objective of lifetime prediction, it is assumed (Fig. 2) that crack initiation (Ref 36) is associated with *microscopic* crack formation, that is, well below a depth of 2 mm (80 mils), at localized corrosion or mechanical defect sites; such sites are related to, for instance, pitting or intergranular attack that may have dimensions of the order of 10 to 100 μm (0.4 to 4 mils), or scratches, weld defects, or design notches. The latter mechanical/design defects will exist at the time of construction, and it is assumed that the former undetectable microscopic initiation sites will exist relatively early in the life of larger-section components. Therefore, the problem of life prediction for larger-section components narrows down to understanding the growth of small cracks from each of these geometrically separated crack-initiation sites, and the coalescence of these small cracks to form a major crack that may then accelerate or arrest depending on the specific material, environment, and stress conditions. For the cracking systems relevant to BWRs this crack coalescence and subsequent growth of a single crack occurs, as shown in Fig. 3 (Ref 37), at crack depths of 50 μm (2 mils), which is well below normal

Fig. 2 Sequence of crack initiation, coalescence, and growth during subcritical cracking in aqueous environments. Note that "engineering initiation" corresponds to crack dimensions equal to crack detection capabilities, i.e., function of crack resolution and probability of detection. Source: Ref 36

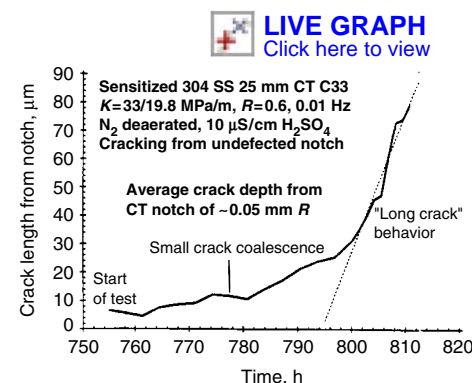

Fig. 3 Observed evolution of intergranular stress-corrosion crack in sensitized stainless steel (SS) compact tension (CT) specimen with single dominant crack being created at ~50 μm depth. Source: Ref 37

commercial crack-detection techniques for systems where the crack detector is well removed from the crack location. Thus, for all practical life-prediction and management purposes, one considers the system conditions that control propagation of an intrinsic single major crack 50 μm (2 mils) deep to a detectable size and the subsequent management of that propagation to ensure maintenance of safety.

There are numerous parameters (Ref 38) that have an effect on EAC propagation in BWR systems (Fig. 4). These initially were characterized (Ref 18) in a macroscopic sense as those that defined the degree of material susceptibility, the "aggressiveness" of the environment, and the magnitude of the tensile stress. This early concept is illustrated in Fig. 5, in which the small region consisting of the overlapping areas of three circles symbolizing the material, environment, and stress factors represents the conditions under which EAC may occur. The presence of these specific factors is a conjoint criterion; that is, all three factors must be present. This explains why the real percentage of, for instance, welded piping exhibiting cracking in a given plant is relatively low. It also indicates that if one factor is missing or reduced sufficiently, then the EAC susceptibility may be significantly reduced. Thus it is evident that there are three obvious methods for mitigating EAC:

- Reducing the tensile stress below some threshold value by new designs or processing techniques
- Changing/eliminating the susceptible material by using an alternate material, alloying addition, surface cladding, material heat treatment, or through processing controls.
- Eliminating or reducing the severity of the corrosive environment below some "threshold" criterion

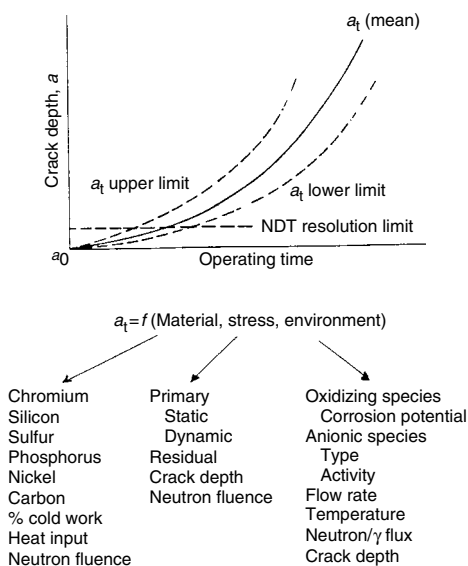

Fig. 4 Materials, stress, and environmental parameters relevant to environmentally assisted cracking in BWRs. NDT, non destructive testing. Source: Ref 38

Tensile Stress Factors

Based on experience with many material/environment cracking systems, the stresses must be tensile to initiate and propagate EAC. Sources of primary and secondary tensile stresses in the BWR reactor components include those produced during both fabrication and reactor pressurization. Fabrication stresses are those introduced during fit-up and assembly in the shop or in the field and include those associated with machining or forming operations (such as surface grinding, welding, or cold straightening). The extent of tensile stress due to some of these sources can be surprisingly large even for those associated with "cosmetic" repair; for example, grinding if done too abusively can introduce surface tensile stresses of the magnitude of the yield point or higher. Weld residual stresses will vary as a function of distance from the weld and through the component thickness (Fig. 6), with the precise variation depending on welding parameters such as heat input, welding speed, number of welding passes, etc. (Ref 18, 39–41). Although these effects are well understood on the basis of data and modeling, the complex parameter interactions can give rise to a scatter in measured residual stresses for a given nominal weld design for which all the relevant welding parameters have not been defined (Fig. 6b). Furthermore, not all sources of tensile stress are immediately obvious; for instance, sufficient tensile stress for EAC may occur due to growth of corrosion product in creviced geometries where there are no other major sources of applied or residual stress (e.g., the crevice regions of certain designs of top guides). Neutron fluence may relax the weld residual stresses in

Fig. 5 The three conjoint factors necessary for producing intergranular stress-corrosion cracking (IGSCC). Appropriate changes in the stress, environment, or material conditions make such a Venn diagram applicable to other modes of EAC. ECP, electrochemical corrosion potential. Source: Ref 18

irradiated core structures but, as is discussed later, neutron irradiation may also introduce deleterious (vis-à-vis cracking susceptibility) grain-boundary sensitization and irradiation-induced hardening (Ref 27–30) and such competing effects may give nonmonotonic cracking kinetics.

Finally, cyclic stresses from vibrations or time-dependent straining from changes in reactor operating mode can also add to the total stress effect on cracking. Such varying stresses are of great importance in initiating cracks or in restarting stopped cracks because they provide continuing plastic strain.

The effect of stress level on the time to failure of sensitized austenitic stainless steels in BWR environments has been studied in detail, and a well-defined dependence of stress on time to cracking has been observed (Ref 19). This relationship is shown in Fig. 7 for furnace-sensitized (24 h at 650 °C, or 1200 °F) type 304 stainless steel subjected to various applied tensile stress modes in 0.2 ppm dissolved oxygenated BWR-type water. As expected, the lower the tensile stress the longer the time to component "failure." It is also apparent that the stress-dependency curve is asymptotic to the at-temperature yield strength of the sensitized material. This laboratory observation led to the development at General Electric (Ref 42) of a "stress rule index" (SRI) for evaluating plant

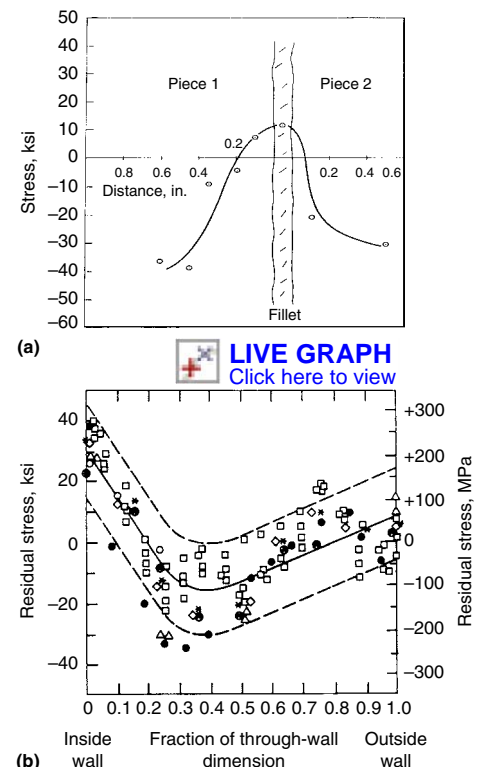

Fig. 6 (a) Variation in longitudinal residual stress adjacent to a weld on the internal pipe surface of a 100 mm (4 in.) pipe. Source: Ref 18. (b) Variation in through-wall residual stress in 700 mm (28 in.) diam schedule 80 piping close to the fusion line. Source: Ref 41

Fig. 7 Stress dependence of intergranular stress-corrosion cracking of a furnace-sensitized type 304 stainless steel in 288 °C (550 °F) water with 0.2 ppm oxygen. Source: Ref 19

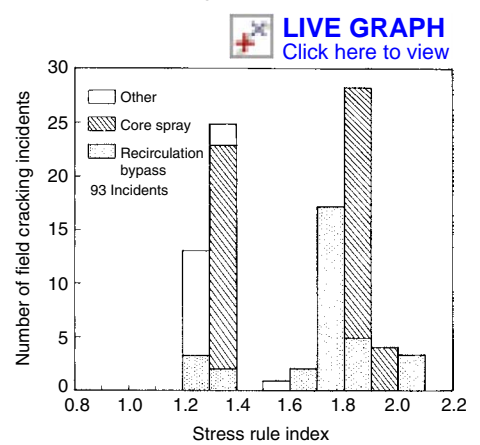

Fig. 8 General Electric stress rule index evaluation of 93 pipe-cracking incidents. Source: Ref 42

performance:

$$\text{SRI} = \left(\frac{P_M + P_B}{S_Y} \right) + \left(\frac{(Q + F + \text{Residual})}{(S_Y + 0.002E)} \right) \quad (\text{Eq 1})$$

where P_M and P_B are the primary membrane and bending stress, respectively, S_Y is the ASME 0.2% offset yield stress at the operating temperature, Q represents the secondary stress (includes thermal), E is the ASME code elastic modulus at applicable temperature, and Residual equals the sum of all sources of residual stress.

Based on observations of numerous cracking incidents in type 304 stainless steel recirculation and core spray lines (Fig. 8), an allowable-stress criterion was defined such that the SRI value must be less than 1.0 to avoid cracking in this class of component. Different limiting SRI values were defined for the onset of cracking in other components, for example, creviced safe ends, and materials of construction.

As discussed earlier, the “failure time” for initially smooth specimens is largely controlled by the propagation rate (Fig. 2) of cracks with dimensions initially well below normally detectable values. An early compilation (Ref 43) of crack-propagation-rate data (da/dt) as a function of stress-intensity factor (K) for sensitized stainless steel in oxygenated water at 288 °C (550 °F) is shown in Fig. 9. Also shown in this figure is the “USNRC disposition curve” (Ref 20) to be used (Ref 44) for disposition of cracks in BWR piping. In Fig. 9:

$$da/dt = 3.590 \times 10^{-8} K^{2.161} \text{ in./h} \quad (\text{Eq 2})$$

where K is the stress-intensity factor in units of $\text{ksi}\sqrt{\text{in.}}$ and da/dt is the crack-propagation rate in units of in./h.

It is apparent that there is a significant variance in the data set that may be attributed to the different degrees of the materials grain-boundary sensitization and range of the dissolved oxygen

Fig. 9 Crack-propagation-rate data for sensitized stainless steel as a function of stress intensity in oxygenated 288 °C (550 °F) water. Source: Ref 43

content in the water. The corresponding data set for a more controlled oxygen content in the range 0.1 to 0.3 ppm, which is more representative of that in BWR water in the recirculation piping, is shown in Fig. 10 (Ref 38, 45);

Fig. 10 Crack-propagation-rate/stress-intensity dependence for sensitized stainless steel in 288 °C (550 °F) water with 0.2 ppm oxygen and conductivity of 0.3–0.5 μS/cm. Note the insertion of theoretical relationships (discussed later) and the NRC regulatory relationship used for structural integrity evaluations. NRC, Nuclear Regulatory Commission. Source: Ref 38, 42, 43

the variance is reduced and the USNRC disposition line (Eq 2) approximates the mean of this data set. It is important to point out that the crack-propagation rates are relatively low compared to those in other classical stress-corrosion systems (e.g., copper alloys in ammoniacal solutions and mild steel in carbonate/bicarbonate solutions) and, given the logarithmic scale in Fig. 10, it would take a considerable experimental time to make an unambiguous case for the existence of a “threshold K_{ISCC} ” below which the crack-propagation rate is “zero.” However, a stress-intensity value can be quoted that corresponds to a very low propagation rate that is “acceptable” over many years of operation. As is discussed later, this “pseudo- K_{ISCC} ” value is not a constant since its value will depend on the specific values of other system parameters.

Material Factors

As indicated in Table 3, the structural materials for the RPV, the reactor internals, and the ancillary piping are ferritic carbon steels or low-alloy steels, and austenitic stainless steels or nickel-base alloys. The RPV is fabricated by welding low-alloy steel plate (e.g., A533 grade B, SA302 grade B), with the nozzle penetrations being forged A508 class 2. Surfaces of the low-alloy steel that are exposed to the water are clad with an austenitic duplex stainless steel (e.g., types 308, 309) for corrosion resistance, although in some of the earlier BWR designs this cladding was absent in the upper-head region on the pressure vessel.

Lower-temperature piping (e.g., the feedwater piping) is generally carbon steel (e.g., SA333 grade 6) whereas the higher-temperature piping comprises welded austenitic stainless steel. The original piping in the United States was predominately type 304 stainless steel (with type 308 weldments), but over the years this has been replaced by lower-carbon L-grade or nuclear-grade (NG) stainless steels that have less susceptibility to grain-boundary sensitization (described below). Core internals such as the core shroud, top guide, and so forth are all wrought and welded austenitic stainless steels of various grades. Stabilized stainless steels such as types 321 or 347 have been used in Germany from the time of construction for the piping and core internals, respectively. Nickel-base alloys are used for nozzle safe ends (e.g., alloy 600) and weld surface preparation butters or weldments (e.g., alloys 82 or 182) for joints between dissimilar ferritic and austenitic stainless steels components.

All of the austenitic alloys are susceptible to a phenomenon known as “grain-boundary sensitization” when heated during fabrication in the temperature range approximately 550 to 850 °C (1000 to 1550 °F). This sensitization increases the susceptibility to intergranular localized corrosion and cracking in 288 °C (550 °F) BWR water due to the chromium depletion that occurs adjacent to the grain-boundary chromium-rich carbide ($M_{23}C_6$) precipitates. This phenomenon is understood in terms of the equilibrium relationships between the metal-matrix and carbide precipitates in an 18Cr-8Ni alloy as shown in Fig. 11 (Ref 46). This simplified phase diagram indicates that the carbon should remain in solid

solution over the temperature range shown provided the carbon is less than approximately 0.03 wt%. Austenite-containing carbon in excess of 0.03 wt% should precipitate $M_{23}C_6$ upon cooling below the solubility line. However, at relatively rapid rates of cooling, this precipitation reaction is partially suppressed, and the room-temperature microstructure is characterized by austenite supersaturated with carbon. If this supersaturated austenite is reheated to elevated temperatures within the ($\gamma + M_{23}C_6$) field, further precipitation of the chromium-rich $M_{23}C_6$ will take place preferentially at the austenite grain boundaries. Certain time-temperature combinations will be sufficient to precipitate this chromium-rich carbide, but will be insufficient to rediffuse the larger chromium atoms back from the grain matrix into the austenite near the carbide in the grain boundaries. The net result is the formation of envelopes of chromium-depleted austenite around the carbide (Fig. 12), which in certain environments will not resist intergranular attack and IGSCC. The sensitized regions adjacent to a weld are known as the heat-affected zone (HAZ) (Fig. 13), and it is within this zone where the grain boundaries are in such a chromium-depleted condition that the IGSCC is concentrated (Fig. 14).

This attack, when the chromium depletion is caused by the temperature/time combinations encountered during welding, has been known as

Fig. 11 Solid solubility of carbon in an Fe-18Cr-8Ni alloy. Source: Ref 46

Fig. 12 Grain boundary in sensitized type 304 stainless steel. Source: Ref 19

“weld decay.” However, more modern practice is to use the term “sensitized” to describe chromium depletion, irrespective of whether it has resulted from slow cooling, postweld heat treatment (PWHT), a process designed to reduce weld residual stress in low-alloy steel pressure vessels, elevated-temperature service, or welding. It is important, however, to distinguish between these sensitization definitions because the stress-corrosion response differs with different heat treatments. For example, “furnace-sensitized” type 304 stainless steel imparted by holding at a sensitization temperature is somewhat more susceptible to IGSCC than “weld-sensitized” material in an oxygenated pure water environment because of the higher integrated time at temperature and, hence, the degree of chromium depletion at the grain boundary.

The distance of the crack in the HAZ from the weld fusion line is governed by the material composition and heat input combinations, which maximize the degree of grain-boundary chromium depletion, and the weld joint design, total heat input during welding, and stress relief, which determine the tensile residual stress. In earlier piping systems, for example, where fairly high carbon content steels were common (e.g., 0.05%) the intergranular crack was located approximately 5 mm (200 mils) from the weld fusion line, but with the use of lower-carbon L-grade steels and refined welding practices the corresponding distance is considerably less and is governed by the strain gradient immediately adjacent to the weld fusion line.

From a life-prediction viewpoint, it is important that such sensitization phenomena be

Fig. 13 Location of intergranular stress-corrosion cracking (IGSCC) in heat-affected zone (HAZ) of type 304 pipe. OD, outside diameter; ID, inside diameter. Source: Ref 19

Fig. 14 Pipe test results showing intergranular stress-corrosion cracking in a 400 mm (16 in.) type 304 pipe heat-affected zone. Source: Ref 19

quantifiable. This has been the objective of extensive investigations over many decades, with focus on predicting the depleted chromium profile adjacent to the grain boundary as a function of alloy composition, cold work, isothermal temperature/time combinations, and welding history (heat input, component size, number of weld passes, etc.) (Ref 47–51). Alternatively, the extent of chromium depletion may be characterized in terms of the amount of intergranular attack measured by a number of nondestructive electrochemical tests (Ref 52–54).

Grain-boundary chromium depletion may also occur in the grain boundary without the $Cr_{23}C_6$ precipitation that is governed by the thermal equilibrium arguments given previously. This may occur due to the impact of neutron irradiation; the physics of this has also been the object of intense analysis (Ref 27–30) since this depletion, together with irradiation-induced metalloid segregation, can further reduce the IGSCC resistance over that associated solely with thermal sensitization. See the article “Effect of Irradiation on Corrosion and Stress-Corrosion Cracking in Light Water Reactors” in this Volume for additional information on this topic.

As mentioned in the section “Background to Problem” in this article, the ferritic alloys may, under fairly limited environmental, material, and stressing conditions, undergo intergranular cracking down prior austenite grain boundaries. The reason for this preferred cracking path is unknown, but is likely associated with metalloid (e.g., phosphorous, carbon, sulfur) segregation to these grain boundaries during fabrication in a manner akin to that in prior austenite grain boundaries of bainitic turbine rotor and disc NiCrMoV or CrMo steels. In the majority of cases, however, the cracking mode is transgranular with the “material sensitivity” being determined by the MnS precipitate size and distribution (Ref 54), and the Al/N alloying content, which affect dynamic strain aging at a given operating temperature (Ref 32, 55). These issues are expanded upon later, but relate to the activity of S^{2-} anions that can be created and retained at the crack tip and the degree of anelasticity in this region.

A final material parameter of importance vis-à-vis cracking sensitivity of both ferritic and austenitic alloys is the yield stress. A considerable amount of investigation on a variety of materials of construction in light water reactors (LWRs) has indicated that as the yield stress is increased either because of irradiation, cold work, or thermomechanical treatment, the EAC propagation rate in BWR environments increases, with potential changes from an intergranular to a transgranular cracking morphology (Fig. 15) (Ref 56). These effects may be localized. For example, the cracking susceptibility may be increased due to strain mismatch across grain boundaries in the HAZ; in this case the susceptibility may be decreased by appropriate thermomechanical treatment to control such high-angle grain-boundary structures. Another well-recognized example of localized cracking

due to yield stress effects is that due to abusive surface grinding that leads to hardened surfaces in which transgranular cracks are easily initiated and propagate approximately 100 μm (4 mils) (depending on the extent of grinding) before transitioning to the normal intergranular mode in the softer underlying matrix. Finally, the straining imparted by weld shrinkage in the HAZs can also produce susceptibility to IGSCC even though there is no sensitization present.

Environmental Factors

The recirculating water coolant in a BWR undergoes radiolysis in the reactor core. The majority of the hydrogen produced in this process is preferentially partitioned to the steam phase, leaving a more-than-stoichiometric amount of dissolved oxygen in the water; this amount is about 0.2 ppm under normal BWR

Fig. 15 Crack-propagation rate for nonsensitized stainless steels in simulated boiling water reactor water at 288 °C (550 °F) as a function of yield stress. Source: Ref 56

Fig. 16 Relationship between electrochemical corrosion potential (ECP) and dissolved oxygen content. Data from operating reactors, with the different symbols being associated with specific plants. Source: Ref 38

operating conditions. The oxidizing potential of the environment is further increased by the presence of 0.2 to 0.4 ppm dissolved hydrogen peroxide, which is also produced in the core. The corrosion potential of the reactor structural members is controlled by the reduction and oxidation reactions occurring on the metal surface; these reactions are dominated by the reduction of the dissolved oxygen and hydrogen peroxide, and the oxidation of the 0.02 ppm hydrogen that remains in the liquid phase. The specific value of the corrosion potential of the metal surface, which is crucial to the thermodynamics and kinetics of the material degradation modes, is a function of the state of the metal surface (e.g., oxidized versus freshly machined), dissolved gas concentrations, the water flow rate, and the temperature. A representative relationship (Ref 38) between corrosion potential for oxidized stainless steel and the dissolved oxygen content is shown in Fig. 16; these data were obtained from an operating BWR plant and show considerable variability, indicative that the dissolved oxygen content is not the only controlling variable. This factor is emphasized in Fig. 17, showing the significant impact on the corrosion potential of the dissolved hydrogen and hydrogen peroxide concentrations (Ref 57). A further variable of importance is the flow rate of the water past the metal surface, since the reactant concentrations and the resultant reaction rates at that surface are dominated by liquid diffusion control. Very similar corrosion potential versus dissolved oxygen content relationships to those illustrated in Fig. 16 and 17 are observed for low-alloy steels and nickel-base alloys, confirming the common controlling processes of dissolved oxygen and hydrogen peroxide reduction, and of hydrogen oxidation on these structural material surfaces.

The corrosion potential is crucial in determining the resultant EAC susceptibility of aus-

tenitic and ferritic alloys in BWR environments; this is illustrated in Fig. 18 and 19 for SCC of sensitized stainless steel and SA333 grade 6 carbon steel, respectively. It is apparent from

Fig. 17 Laboratory data indicating variation of corrosion potential type 316 of stainless steel with dissolved hydrogen peroxide and hydrogen in 288 °C (500 °F) water. Source: Ref 57

Fig. 18(b) and 19 that there is a very high sensitivity of the crack-propagation rate on the corrosion potential, thereby suggesting a prime mitigating parameter for EAC. Caution should be given, as with the concept of K_{ISCC} discussed earlier, in defining an absolute value of corrosion potential below which EAC “will not occur”; for instance, early investigations (Fig. 18a) ascribed a value of -230 mV standard hydrogen electrode (SHE) as a “threshold potential” for EAC of stainless steels based on data from accelerated slow-strain-rate tests in operating reactors. There are two concerns in this absolute definition. The first is that in many cases (see, for instance, Fig. 18b) cracking can occur, albeit at very slow propagation rates, at corrosion potentials below the “threshold” corrosion potential value; such rates would not be resolvable in an accelerated test such as that used for the data collection shown in Fig. 18(a). The second is that, although under most operating conditions -230 mV (SHE) is a conservative limiting value for constant load/deflection conditions, the absolute “threshold” value will depend on the interactions of other system variables (e.g., stress/strain rate, water purity, alternate alloys, irradiation flux/fluence, etc.) and, in fact, more positive threshold values of corrosion potential than -230 mV (SHE) may be appropriate for many current operating conditions.

Corrosion problems may be encountered on metal surfaces where cation or anion concentration and excessive metal salt/oxide precipitation occurs; these phenomena may be associated with, for instance, the presence of crevices in oxidizing environments, or boiling at heat transfer surfaces. To minimize these potential localized corrosion problems, the BWR water coolant purity is high. For instance in most current operating reactors the coolant purity approaches that of theoretical-purity water, that is, room-temperature conductivity 0.055 $\mu\text{S}/\text{cm}$, with dissolved chloride and sulfate activities

maintained below 5 ppb. Early observations (Ref 25, 26) indicated that the incidence of plant component cracking correlated well with the plant reactor water conductivity or coolant impurity level. Subsequent laboratory measurements on the austenitic and ferritic alloys confirmed correlations between the crack-propagation rate and conductivity under both steady-state and transient water purity conditions as shown in Fig. 20 and 21, respectively (Ref 38, 59).

The relationships between the crack-propagation rate and the corrosion potential and conductivity shown in Fig. 18(b) and 19 to 21 indicate that it is not the conductivity of the bulk water that is of fundamental importance, but rather the crack-tip (non- OH^-) anionic activity. This crack-tip activity will be increased over the bulk value by a factor of 10 to 50 (Ref 38) due to potential-driven diffusion down the crack since the crack mouth corrosion potential under “normal” oxidizing water chemistry conditions may be of the order of $+50$ mV (SHE), while the crack-tip potential will be of the order of -500 mV (SHE). Such a potential-driven increase in (non- OH^-) anionic activity at the crack tip will be accompanied by a decrease in pH to maintain local electroneutrality. These combined effects of increased anionic activity and increased acidity at the crack tip will affect the oxidation kinetics occurring in this region and thereby the crack-propagation rate.

Strong acid-forming anions such as sulfate (Ref 60–73) or chloride (Ref 61, 74–76), which originate from resin decomposition in the demineralizer beds, leakage of impurities in defective condenser tubes, and so forth, can have a significant effect on the crack initiation and propagation rate of all the ferritic and austenitic alloys in BWR environments. The theoretical

predictions of the effect of corrosion potential and anionic activity on the IGSCC propagation rate of sensitized type 304 stainless steel stressed at 27.5 $\text{MPa}\sqrt{\text{m}}$ (25 $\text{ksi}\sqrt{\text{in.}}$) is indicated in Fig. 22 for sulfate and chloride anions. It is seen that under “normal” water chemistry conditions corresponding to a corrosion potential of approximately $+50$ mV (SHE) for a recirculation line, increasing the anionic activity from a preferred operating value of <5 to 20 ppb or, in a worst case scenario of 100 ppb, the crack-propagation rate would be predicted to increase by up to two orders of magnitude under oxidizing conditions. Under lower corrosion potential conditions associated with hydrogen water chemistry (HWC) with or without noble metal technology, it is predicted and confirmed (Ref 72) that the increases in propagation rate for stainless steels due to such anionic transients are markedly lower. Preliminary data for nickel-base alloys (Ref 73) indicate that the beneficial effect of lowering the propagation rate in sulfate-containing environments by decreasing the corrosion potential may not be quite as effective as observed in stainless steels, indicating possibly a change in cracking mechanism at low potentials to that pertinent to nickel-base alloys in PWR primary side environments.

Although cationic impurities will not concentrate to the crack tip due to potential-driven mass transport, they can have some effect on crack initiation and shallow crack propagation. For instance, bulk pH changes either side of neutral can be detrimental to crack initiation (Ref 72, 77) with there being more degradation for the acidic shift. However, these changes in cracking susceptibility are likely to be minor in practice since pH changes in the BWR coolant will be limited if the reactor coolant conductivity and anionic activity specification limits are maintained.

Zinc, which may be present in the reactor coolant due to corrosion of the brass condenser tubes or purposely added to control radioactive ^{60}Co buildup on the metal surfaces, may increase the cracking resistance of stainless steel, alloy

Fig. 19 Predicted (Ref 60) and observed (Ref 61, 62) dependency of the stress-corrosion crack-propagation rate on corrosion potential for A508 steel containing 0.01% S strained at 1 to 1.5×10^{-6} s^{-1} in 288°C (550°F) water with conductivity of 0.2 $\mu\text{S}/\text{cm}$

600, and alloy 182 (Ref 78–81) in the doping range 5 to 10 ppb and is effective even in the presence of sulfate and chloride contamination. This beneficial effect is attributed to increases in the fracture strain of the surface oxide and the repassivation rate at the crack tip (Ref 82) which, as is discussed later, are fundamental to the crack-propagation process.

The complex interactions between the cracking susceptibility of a given structural alloy and the dissolved oxygen, hydrogen peroxide and hydrogen concentrations, specific anionic impurity concentrations, temperature, and stressing state, that is, constant versus dynamic loading, are quantifiable and applicable to plant “on-load” operations and, as is discussed later, practical mitigation actions may be defined. Under transient plant operations, such a startup and shutdown, the situation becomes more complicated since, not only are these system parameters (e.g., temperature, dissolved oxygen content, etc.) continuously changing, but there is the possibility that the rate-controlling steps in the cracking mechanism may also change. This created some early concern given the “lore” that EAC problems in operating plant (not just nuclear reactors) can generally be related to such transient operating conditions. This concern was addressed in the early 1980s (Ref 83–90) with the conclusion that, although the EAC susceptibility in BWRs may be increased for both ferritic and austenitic alloys (especially at intermediate oxygen and temperature combinations encountered during plant startup), the cumulative damage during this transient period was minor compared to the damage accumulated during the much longer “on-load” period. One recommendation from these studies, however, which has been widely adopted, is the practice of deaerating the coolant before and during the startup procedure.

Prediction of EAC in BWRs

The previous section discusses the primary materials, environment, and stress parameters that, in isolation, have an effect on the cracking susceptibility of ferritic and austenitic structural alloys in BWRs. This discussion does not lead directly, however, to the quantification of the primary and secondary interactions between these parameters that are necessary for the development of a prediction algorithm of the general form:

$$\text{Crack dimensions} = f(\text{materials, stress, environment}) \text{ time} \quad (\text{Eq 3})$$

where the materials, stress, and environment parameters listed in Fig. 4 may change with structural dimensions and time.

There are two basic approaches that have been taken in deriving such a generic life-prediction algorithm. The first is the classic method of developing a multiparameter correlation function that encompasses all relevant plant or laboratory data. The second is based, first, on developing a quantitative understanding of the mechanism of cracking, followed by qualification of this mechanisms-informed analysis via comparison with the relevant single and multi-effects data sets.

Data-Based Life-Prediction Approaches

These approaches rely on the development of correlation functions based on laboratory or plant operational data. Although sound in principle such approaches are very much limited by the quality, and thereby the variance, of the data upon which the correlation is based. For instance, data for cracking of stainless steel

pipng as a function of plant operational time (Fig. 23) can exhibit extensive scatter because of an imprecise definition of the system upon which the data was derived. Thus, although analyses of trends in plant behavior as a function of alloy type or water chemistry are useful for predicting the likelihood of a particular failure mode in a given component and for developing risk-informed component inspection procedures (Ref 91), they are insufficient for development of deterministic relationships such as described in Eq 3 or Fig. 4.

Analysis of laboratory data to derive Eq 3 promises greater success than that of plant data since, in principle, such experimental data can be obtained under more stringent system definition and control. Unfortunately, as exemplified by the crack-propagation-rate data for stainless steels in Fig. 9, the expected decrease in data variance is not always achieved, either because at the time that the data was collected the techniques for accurately measuring crack-propagation rates relevant to 40 year component lives had not been developed or because the experimental system was not adequately defined or controlled. For instance, uncontrolled or unmonitored changes in coolant purity can give substantial changes and, thereby, variance in the cracking response of all the BWR structural alloys (Fig. 20). Similarly, the lack of measurement of corrosion potential, plus the practice in the 1970s and 1980s of monitoring solely “dissolved oxygen content” led to inadequate control of the experiment since the corrosion potential could vary by significant amounts and, thereby, lead to large changes in cracking response (Fig. 18 and 19) for relatively small changes in total oxidant concentration and water flow rate. Consequently in more recent times extensive attention has been paid to experimental control and data quality (Ref 92, 93), and old data have been examined and, where necessary, censored with respect to agreed-upon quality-control criteria and adequate system control. Such censoring activities can decrease the data variance at the cost of substantially reducing the number of data points that can be analyzed (Ref 92–94), thereby having an impact on the statistical treatment of these data.

Mechanisms-Informed Life-Prediction Approaches

Development of mechanisms-informed models to answer the basic life-management questions posed in Fig. 1 and the related text is viable due to the marked increase in mechanistic understanding of the EAC process that has occurred since the late 1980s and the availability of improved experimental and analytical techniques (e.g., electrochemistry, electron microscopy, material analysis) necessary to quantify the model input and to verify the model predictions.

A requirement at the start of such a mechanisms-informed development is that there be a working hypothesis for crack propagation, which must be then quantitatively validated against well-controlled data. The prime contending hypotheses in the late 1970s were the slip-oxidation, film-induced cleavage, and hydrogen embrittlement models (Ref 95). Although thermodynamic arguments can be made to support all three models for ductile alloys in BWR systems, the soundest kinetic arguments are those based on the slip-oxidation model after considering the range of environments, stressing modes, and materials relevant to BWR operations (Ref 59, 84, 96).

The slip-oxidation model equates, via Faraday's relationship, crack propagation to the oxidation charge density at the crack tip that is associated with the transformation of the metal to the oxidized state (e.g., MO or M_{aq}^{2+}). As shown in Fig. 24, the relevant phenomena in the crack enclave are (Ref 59):

- The creation of a crack-tip environment that may be markedly different from the bulk environment due to the mass transport (controlled by potential drop, convection, etc.) of sol-

vated cations, water, and anions within the crack enclave. A significant driver in this process is the potential drop down the crack length, which exists due to the highly oxidizing conditions at the crack mouth and the deaerated, reducing conditions at the crack tip.

- The metal oxidation rate of the crack-tip alloy whose composition may be significantly different from the bulk alloy and which is being dynamically strained by the residual or applied loads.

There are two basic approaches that have been taken to quantify these processes. The first is that taken by General Electric and formulated in the PLEDGE model (Plant Life Extension Diagnosis by GE). This model equates the propagation rate to the oxidation kinetics of the strained crack-tip material in the *localized* crack-tip environment (Fig. 24a) (Ref 38, 59, 84); it emphasizes the importance of the corrosion potential at the crack mouth as being one controlling component in creating a mechanism for anion and acidity concentration at the crack tip (Fig. 24b). The second approach is that of Macdonald et al. (Ref 97–99), which *directly* couples the total oxidation current emanating from the strained crack tip with the reduction rates (involving oxygen and hydrogen peroxide) at the crack mouth. This Coupled Environment Fracture Model (CEFM) and the PLEDGE model predict the same general dependencies of SCC for stainless steels on, for instance, corrosion potential, water conductivity, sensitization, and stress intensity, although in several cases there are significant differences in predicted cracking behavior at the extremes of these system parameters.

For brevity, a more detailed description of the prediction capabilities is confined to the PLEDGE model, and its development for EAC in

Fig. 25 Oxidation current density versus time relationship for a strained crack tip. Source: Ref 59

the stainless steel/water system and its logical expansion to cover irradiation-assisted cracking (due to changes in material and environmental parameters in the model), and EAC in nickel-base alloys and low-alloy ferritic steels.

The change in oxidation current density with time (and hence oxidation charge density) following the rupture of a protective film at the crack tip is shown in Fig. 25. Initially, the oxidation rate and, hence, crack-propagation rate will be rapid, controlled by activation or diffusion kinetics as the exposed metal dissolves (Ref 59). However, in most of the cracking systems of interest in the BWR, a protective oxide or salt is thermodynamically stable and will reform via solid-state oxidation and/or precipitation from solution on the bare surface. As a result, the oxidation (dissolution) rate, i_t , will fall from the bare surface value, i_0 , following a time period, t_0 , according to:

$$i_t = i_0 (t/t_0)^{-n} \quad (\text{Eq 4})$$

Consequently, the rate of total oxidation charge density and, hence, crack-tip advance will

slow with time following the initial rupture of the crack-tip oxide. Thus, crack propagation can only be *maintained* if the film rupture process reoccurs. Therefore, for a given crack-tip environment, potential, and material condition, the crack-propagation rate will be controlled by both the change in oxidation charge density with time and the frequency of film rupture at the strained crack tip. This latter parameter will be determined by the fracture strain of the film, ϵ_f , and the strain rate at the crack tip, $(d\epsilon/dt)_{ct}$. Thus, by invoking Faraday's law, the average environmentally controlled crack-propagation rate, da/dt , is related (Ref 38, 59, 96) to the strain rate at the crack tip, $(d\epsilon/dt)_{ct}$, the oxidation rate at the bared crack tip, i_o , and the repassivation rate parameter, n , via:

$$da/dt = (M/z\rho F)(i_o t_o^n / (1 - n)\epsilon_f^n)(d\epsilon/dt)_{ct}^n \quad (\text{Eq 5})$$

where M and ρ are the atomic weight and density, respectively, of the crack-tip metal, F is Faraday's constant, and z is the number of electrons involved in the overall oxidation of an atom of metal.

Under constant load or displacement conditions, the crack-tip strain rate will be related to the creep processes at a moving crack tip, and under monotonically or cyclically changing bulk strain conditions it will be related to an applied strain rate. Thus, the slip oxidation mechanism may be applied to not only stress corrosion but also strain-induced cracking and corrosion fatigue.

Recognition of the interacting effects of mass transport within the crack enclave, oxidation or reduction rates at the crack tip and crack mouth, and the crack-tip strain rate has proven of great value in identifying the generic system changes that are likely to reduce the extent of a particular EAC problem (Ref 95). For instance, increasing cracking resistance is to be expected by increasing the passivation rate at the crack tip (by control of the corrosion potential/anionic activity combinations or by material composition changes) and by reduction in crack-tip strain rate (by attention to dislocation morphology, the imposed stress history, etc.) (Ref 84, 95). Thus, there is a mechanisms-informed basis for understanding and developing quantitative predictions of the empirical observations of the effects on EAC susceptibility of, for instance, zinc (effect on oxide fracture strain and passivation rate), chloride and sulfate (effect on passivation rate), and so forth. It is also important to point out that these mechanisms-informed arguments meld into the empirical observations of the factors that influence EAC in BWR systems (Fig. 26).

To advance this concept to application to BWR cracking systems, it is necessary to redefine the fundamental Eq 5 in terms of measurable engineering or operational parameters (Fig. 24b). This involves:

- Defining the crack-tip alloy/environment composition in terms of, for example, bulk alloy composition and heat treatment, anionic

concentration or conductivity, dissolved oxygen, hydrogen and hydrogen peroxide contents, or corrosion potential at the crack mouth

- Measuring the reaction rates for the crack-tip alloy/environment system that correspond to the "engineering" system
- Defining the crack-tip strain rate in terms of continuum parameters such as stress, stress intensity, loading frequency, and so forth. There has been extensive work conducted in these areas (Ref 38, 59, 96) for austenitic and ferritic alloys in BWR systems, and the technical details are not reproduced here. Attention is focused on illustrating how these advances have been incorporated into verified, quantitative life-prediction methodologies.

Sensitized Type 304 Stainless Steel

The relevant fundamental reactions pertinent to crack-tip systems have been extensively investigated leading to a quantification of the basic parameters in Eq 5. For stainless steels, this equation for the crack-propagation rate may be simplified to:

$$da/dt = 7.8 \times 10^{-3} n^{3.6} (d\epsilon/dt)_{ct}^n \quad (\text{Eq 6})$$

where da/dt is in units of cm/s, n varies between 0.33 and 1.0, depending on factors discussed below, and the crack-tip strain rate is in units of s^{-1} .

As discussed previously, n , the passivation rate parameter in Eq 4 is controlled by the crack-tip environmental (e.g., pH, potential, anionic activity) and material (e.g., percentage of chromium depletion in grain boundary) conditions. To make this practically useful, n has been reformulated in terms of measurable bulk system parameters such as water conductivity (κ), corrosion potential (ϕ_c)—which, in turn, is a function of the dissolved oxygen and hydrogen peroxide content—and the "electrochemical potentiokinetic repassivation" (EPR) parameter,

Fig. 26 Relationship between the empirical conjoint factors necessary for EAC: stress, environment, and material conditions, and the crack-tip mechanistic factors, oxide rupture frequency, passivation rate, and solution renewal rate. Source: Ref 38, 59, 96

which is related to the chromium depletion in the grain boundary. Thus, as shown in Fig. 27:

$$n = \left\{ \frac{e^{f(\kappa)}}{e^{f(\kappa)} + e^{g(\phi_c)}} \right\}^{h(\text{EPR})} \quad (\text{Eq 7})$$

The crack-tip strain rate, $(d\epsilon/dt)_{ct}$, in Eq 5, may be related to the engineering stress (or stress-intensity) parameters. For instance, under constant load, the crack-tip strain rate is related to the stress-intensity factor, K , via:

$$(d\epsilon/dt)_{ct} = 6 \times 10^{-14} K^4 \quad (\text{Eq 8})$$

where the strain rate is in units of s^{-1} and the stress-intensity factor (K) is in units of $\text{ksi}\sqrt{\text{in.}}$

This formulation of the crack-tip strain rate proved adequate in the early development and application of the model, but it oversimplified the physical fact that as the crack tip advanced the associated stress field activated further dislocation sources. Such activation would increase the crack-tip strain rate by an amount proportional to the crack-propagation rate and the strain profile in front of the crack tip. The resultant crack-tip strain rate would, therefore, be the result of a dynamic equilibrium between this crack-propagation rate-dependent strain rate and the contribution due to exhaustion creep, which would be decreasing with time at the relatively low homologous temperatures relevant to BWR operations, that is:

$$(d\epsilon/dt)_{ct} = (d\epsilon/dt)_{\text{creep}} + (d\epsilon/da) \cdot (da/dt) \quad (\text{Eq 9})$$

where a is the distance in front of original crack tip.

The general validity of the prediction methodology is indicated in Fig. 28, which covers data obtained on sensitized type 304 stainless steel in

Fig. 27 Relationships between n in Eq 6 and 7 and the corrosion potential and bulk solution conductivity for a sensitized ($\text{EPR} = 15 \text{ C/cm}^2$) type 304 stainless steel in water at 288°C (550°F). EPR, electrochemical potentiokinetic repassivation. Source: Ref 38

8 ppm oxygenated water at 288 °C (550 °F) stressed over a wide range of constant load, monotonically increasing load, and cyclic load conditions. The solid line shows the theoretical relationship from Eq 6 and 7 and the appropriate strain-rate formula for the stressing mode. The agreement between prediction and observation illustrates the applicability of the methodology to the whole stress-corrosion/corrosion-fatigue spectrum. The effect of, for instance, coolant (water) deaeration on the relationship between crack-propagation rate and crack-tip strain-rate is shown in Fig. 29. The degree of the predicted and observed beneficial effect of deaeration is very dependent on the strain rate (i.e., stress level and/or degree of dynamic loading), and this has an impact on evaluating the benefit of deaeration and the choice of the test technique that will be used to quantify the benefit. For instance, the factor of improvement (defined as the ratio of the crack-propagation rates in the two environments at a given crack-tip strain rate) decreases with increasing strain rate: thus factors of improvement determined by an accelerated “slow-strain-rate test” (with crack-tip strain rates in the range 10^{-4} to 10^{-6} s $^{-1}$) will significantly underestimate the improvement expected in a plant component subject to weld residual stresses (with crack-tip strain rates less than 10^{-8} s $^{-1}$).

The specific effects of changes in corrosion potential and solution conductivity on the propagation rate under constant load are shown in Fig. 18 and 20; the beneficial effects of improved water chemistry control (by controlling the coolant conductivity or anion content) and coolant deaeration are predictable and quantifiable and thereby lay a solid mechanistic basis for the definition of water chemistry specifications.

Nickel-Base Alloys

The development of prediction models for EAC of nickel-base alloys in BWR systems has been made difficult by the fact that the observed data, against which the prediction models can be validated, either exhibit extreme scatter or were obtained under conditions that do not apply directly to current BWR plant operation (e.g., high conductivity, high stress intensity, corrosion potentials outside range of interest, etc.).

Establishing a mechanistic link between crack-growth rates in stainless steels and ductile nickel-base alloys helps resolve this problem, since it permits the much broader base of data and modeling for stainless steels to provide guidance on the expected cracking susceptibility of nickel-base alloys in BWR systems (Ref 100, 101). Such a mechanistic comparison is reasonable since:

- Intergranular or interdendritic cracking is the dominant failure mode in both the austenitic stainless steels and nickel-base alloys and is associated with chromium depletion at the grain boundary in both alloy classes and hardening or straining. In the case of the

stainless steels, the parameter EPR is used to quantify this depletion phenomenon, as described previously. Such a parameter cannot be measured easily in the nickel-base alloys; thus to use the stainless steel prediction algorithms directly, an “equivalent EPR” value has to be introduced.

- Both alloy systems involve ductile face-centered-cubic structures with similar mechanical properties. Thus it is reasonable to use in preliminary model derivations the same crack-tip strain-rate algorithms for ductile nickel-base alloys as for the stainless steels.
- The solubility of the (NiCr) oxides and (FeCr) oxides are very similar in BWR water and thus from an electrochemical viewpoint the crack-tip system (Fig. 24a) and rate-determining steps in the bare surface oxidation kinetics are likely to be similar for the nickel-base and austenitic steel alloy systems. Thus it is to be expected that the i_o , t_o , and n values in Eq 4 will be comparable, and, hence, the general propagation Eq 5 may be used for nickel-base alloys in preliminary analyses.

Despite these assumptions, the predictions are in reasonable agreement with the observations of stress corrosion and corrosion fatigue in the nickel-base alloy/BWR systems. For instance,

Fig. 28 Observed and theoretical crack-propagation rate versus crack-tip strain-rate relationships for sensitized type 304 stainless steel in oxygenated water at 288 °C (550 °F). EPR, electrochemical potentiokinetic repassivation. Source: Ref 38, 59

Fig. 29 Observed and theoretical crack-propagation rate versus crack-tip strain-rate relationships for stainless steel in aerated and deaerated water. Source: Ref 38, 59

the crack-propagation rate versus water conductivity relationships observed in operating plant at various corrosion potentials for alloy 182 are in reasonable agreement with the theoretical predictions (Fig. 30). In addition, the variation in cracking of alloy 600 access hole covers and shroud head bolts as a function of the average plant conductivity are also reasonably predicted. The data and predictions for these cases are shown in Fig. 31(a) and (b). In Fig. 31(a), the importance of the detrimental effect of excessive

Fig. 30 Comparison between the predicted and observed crack-growth rates versus coolant conductivity for alloy 182 compact tension (CT) specimens exposed to BWR water of varying chemistries

Fig. 31 (a) The predicted and observed effects of average plant water purity on crack incidence in creviced alloy 600 shroud head bolts. (b) Predicted and observed IGSCC on 15 mm (0.600 in.) welded access hole covers

coolant transients is noted even if the average conductivity is subsequently maintained at a low average value.

In conclusion, there is now the methodology to predict the extent of EAC damage for many of the BWR structures, provided the relevant materials, environment, or stressing variables are known, or can be calculated, with sufficient accuracy. This capability offers the opportunity to *proactively* manage the material degradation problems (Fig. 32) by defining cost-effective mitigation actions that may be implemented before costly (Table 2) repairs are necessary.

Mitigation of EAC in BWRs

The following discussion presents several EAC mitigation techniques for BWR components. The mitigation methods are presented under general categories of material solutions, stress solutions, and environmental solutions. A few of the remedies address two of the three necessary conjoint factors illustrated in Fig. 5.

Materials Solutions

The materials solutions to the piping IGSCC concern in the United States consist primarily of replacing the susceptible type 304 and 316 stainless steels with more sensitization-resistant materials, such as types 316 and 304 nuclear grade (NS), redissolving the chromium carbides by solution heat treatment, and cladding with crack-resistant weld metal. Other materials, such as type 347NG, have been used successfully in Europe.

Nuclear-Grade Stainless Steels. The replacement of current piping materials with materials more resistant to sensitization is a straightforward approach to mitigating IGSCC. It is well documented that decreasing the carbon content and increasing the molybdenum content of stainless steel will reduce the kinetics of sensitization

(Ref 102–105). However, type 316NG and type 304NG (with no added molybdenum) stainless steels take this theme a step further. Instead of the nominal 0.03% C maximum of the L-grade stainless steels, (Fig. 11) the nuclear grades are characterized by a maximum carbon content of 0.020%. The second important composition characteristic of type 304NG and type 316NG is the specification of 0.060 to 0.100% N. This modification is designed to recover the decrease in alloy strength due to the reduction of the carbon content. Another successful approach that has been used in Germany is the use of low-carbon niobium-stabilized type 347 stainless steel.

For the nuclear-grade materials, full-size pipe tests have shown that factors of improvement over reference type 304 stainless steel performance can be expected to be at least 50 to 100 times in normal BWR operation (Ref 103). The necessary factors for improvement for the current 40 year service life are approximately 20. Therefore, the replacement of type 304 stainless steel piping with type 316NG, type 304NG, or type 347NG provides substantial resistance to IGSCC. It is important to note that, as discussed previously, materials-based resolutions can be rendered insufficient if there are other secondary aggravating effects; for instance creviced design or the introduction of cold-worked microstructures through various fabrication practices. For example, a data-based life-prediction analysis at one Swedish nuclear plant determined that nearly 50% of failures were attributable to cold work fabrication practices (Ref 91). Normally resistant stainless steels can also suffer IGSCC if good-quality water chemistry in the BWR is not maintained.

Solution Heat Treatment. Immunity against IGSCC of type 304 stainless steel can be provided by eliminating weld-sensitized regions. This can be accomplished by solution heat treatment to redissolve the chromium carbides and eliminate chromium depletion around previously

sensitized grain boundaries (Fig. 11 and 12). Moreover, solution heat treatment will eliminate detrimental cold work and weld residual stress in the pipe. Following a butt-welding operation, the entire pipe segment is solution annealed at 1040 to 1150 °C (1900 to 2100 °F) for 15 min per 25 mm (1.0 in.) of thickness but not less than 15 min or more than 1 h, regardless of thickness. The pipe segment is then quenched in circulating water to a temperature below 205 °C (400 °F). Solution heat treatment is generally limited to those weld joints made in the shop where heat treatment facilities are available, because of dimensional tolerance consideration, size constraints of the vendor facilities (furnace and quench tank), and cooling rate requirements (dead end legs).

Corrosion-resistant cladding achieves its resistance to IGSCC by using the IGSCC resistance inherent in duplex austenitic-ferritic weld metals (Ref 103). Although the carbide precipitation observed in the HAZ inside surface is also present in the weld metal, the nature of the duplex structure of the weld metal provides resistance to IGSCC in the BWR. In fact, IGSCC propagating from the weld HAZ is generally blunted when it reaches the weld metal if sufficient ferrite is present. As shown in Fig. 14, the cracking will actually curve away from the weld metal. Field experience has indicated that in the as-welded condition very little ferrite is required to prevent IGSCC. These results and numerous laboratory data generated on welded and furnace-sensitized type 308 and type 308L weld metal prompted the conclusion that a minimum amount of ferrite (8%) must be present to provide a high degree of resistance to IGSCC in BWR environments. As with type 304 stainless steel, reducing the carbon level is also beneficial.

In the corrosion-resistant cladding technique, type 308L weld metal is applied using controlled heat input process to the inside surface of the pipe at the pipe weld ends before making the final field weld. This duplex weld metal covers the region that will become sensitized during the final weld process, thus providing IGSCC resistance by maintaining low carbon and a sufficient ferrite level in the region that would normally be sensitized.

Weld overlay repair is similar to corrosion-resistant cladding in that it uses layers of IGSCC resistant duplex weld metal (Ref 104). For cases where alloy 182 is to be overlaid, alloy 82 or 52 weld metal is used. The most significant difference is that the layer of weld metal is placed on the outside surface of the pipe while the pipe is being cooled internally with water and is used to prevent an existing crack from penetrating through the wall. The weld overlay is also applied as a structural reinforcement to restore the original piping safety margins (Fig. 33). An equally important effect of the weld overlay is that it produces a favorable (compressive) residual stress pattern that can retard or arrest crack growth.

The weld overlay technique has the potential for being the most cost-effective method as

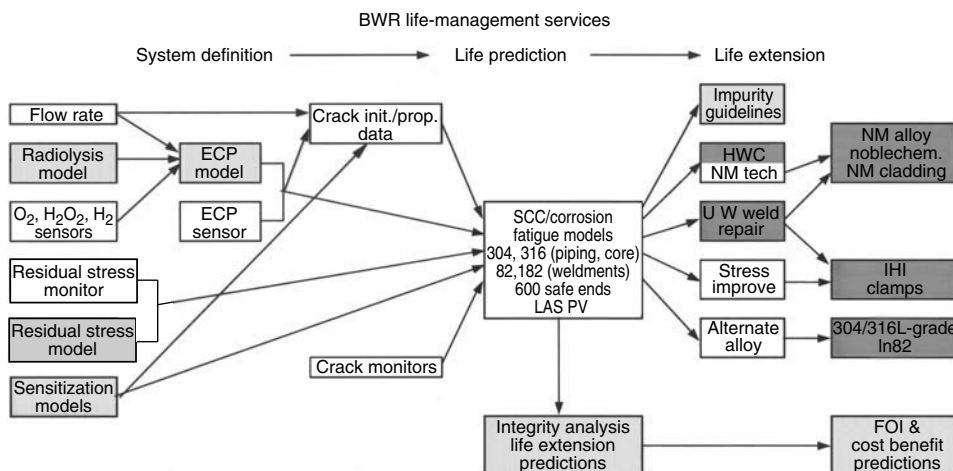

Fig. 32 Proactive management scheme for addressing environmentally assisted cracking (EAC) problems and assessing the cost-effective mitigation action

compared to other repair techniques (pipe replacement, solution heat treatment, corrosion-resistant cladding), which require draining of the system. For additional information, see the article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook*.

Tensile Stress Reduction Solutions

The tensile stress solutions primarily affect the weld residual stress profile by placing the inner surface weld residual stress in compression. These solutions, which are discussed below, include heat sink welding, induction heating stress improvement, and last-pass heat sink welding.

Heat Sink Welding. If a pipe can be welded without producing a sensitized structure and high residual tensile stresses in the weld HAZ, the resultant component will be resistant to IGSCC in the BWR environment. The heat sink welding program developed procedures that reduce the sensitization produced on the inside surface of welded pipe and, more important, change the state of surface residual welding stresses from tension to compression. This approach can be used in shop or field applications. Heat sink welding involves water cooling the inside surface of the pipe during all weld passes subsequent to the root pass or first two layers. Water cooling can be applied by using flowing or turbulent water, by spray cooling through a sparger placed inside the pipe, or, in a vertical run, by still water. Laboratory type 304 stainless steel butt welds have been produced to evaluate the inside surface heat sink welding techniques (Ref 105). Residual stresses were measured with strain gages. It was found that in a variety of pipe sizes the inside surface tensile residual stress is reduced substantially or changed from tension to compression as a result of this approach. Heat sink welding, as mentioned previously, has a secondary benefit in that it reduces the time at temperature for sensitization due to the presence of the cooling water heat sink.

Induction Heating Stress Improvement. This technique changes the normally high tensile stress present on the pipe inside surface of weld HAZs to a benign compressive stress (Ref 106, 107). This process involves induction

heating of the outer pipe surface of completed girth welds to approximately 400 °C (750 °F) while simultaneously cooling the inside surface, preferably with flowing water (Fig. 34). Thermal expansion caused by the induction heating plastically yields the outside surface in compression, while the cool inside surface plastically yields in tension. After cool down, contraction of the pipe outside surface causes the stress state to reverse, leaving the inner surface in compression and the outside surface in tension (Fig. 35).

Qualification of the effectiveness of induction heating stress improvement has been accomplished by establishing (Ref 104, 107):

- Induction heating stress improvement treatment reliably reduces normally high tensile inside surface residual stresses to a zero compressive state.
- Full-size environmental pipe testing and residual stress tests have demonstrated that

Fig. 34 Heating and cooling process for induction heating stress improvement

Fig. 35 Residual stress comparison for induction heating stress improvement

these beneficial residual stresses result in a large improvement in IGSCC resistance.

- Metallurgical investigations have shown that an induction heating stress improvement treatment produces no adverse effects. No increase in sensitization is found, and no significant variation in mechanical properties occurs.
- A minimum life of 12 fuel cycles (~216 months) has been measured on induction heated stress improved precracked pipes in the laboratory if the initial cracking does not exceed about 20% of wall thickness.

Last-Pass Heat Sink Welding. As discussed in the previous section, induction heating stress improvement is an IGSCC mitigation technique that favorably alters the weld residual stress pattern. The welding torch is the heat source that initially produces the undesirable residual stress that induction heating stress improvement counterbalances. Analysis was able to establish that this residual stress state could be made compressive by the introduction of inside surface water cooling during the welding operation. Cooling during the entire welding process (heat sink welding) or just during the last pass could be effective in reversing the residual stresses analogous to the induction heating stress improvement process. Qualification of the last-pass heat sink welding process consisted of magnesium chloride ($MgCl_2$) residual stress tests, which verified that the last-pass heat sink welding process does produce compressive residual stresses uniformly around the pipe circumference (Ref 108). Stress-relief strain-gage measurements quantified the compressive axial stress and revealed that the stresses were compressive up to about 50% through-wall.

Finally, intergranular SCC improvement was evaluated by using pipe tests performed at applied stresses above yield in a high-oxygen (8 ppm) high-temperature (288 °C, or 550 °F) water environment. As shown in Fig. 36, at the end of the program period, the pipes had been on test for more than 5500 h, demonstrating a factor of more than 5.5 and more than 6.5 improvement, respectively, at the two test stresses of 193.7 and 211 MPa (28.1 and 30.6 ksi), respectively. This factor of improvement approaches that determined for induction heating stress improvement.

Environmental Solutions

Water Purity Control. As indicated previously in Fig. 20 to 22, 30, and 31, the BWR coolant conductivity or purity has a profound impact on the degree of EAC susceptibility for all the major materials of construction in the BWR system. As a result, water chemistry guidelines recommend maximum limits to the BWR feedwater and recirculation water coolant conductivity and cationic and anionic activities. Action levels (e.g., ultimately reactor shutdown) are prescribed should these limits be exceeded by specific amounts for given time periods. As a result, the purity levels that are maintained in the BWR coolant have markedly improved, with the mean conductivity level of approximately 0.37 $\mu\text{S}/\text{cm}$ observed in 1980 decreasing to approximately 0.10 $\mu\text{S}/\text{cm}$ in 2003 (Fig. 37).

Hydrogen Water Chemistry and Noble Metal Technology. As indicated in Fig. 18, 19, and 22, there is abundant laboratory and plant experience to indicate that the EAC susceptibility will be markedly reduced by decreasing the corrosion potential of the structural material to below -230 mV (SHE) via control of the reduction kinetics associated with the dissolved oxygen and hydrogen peroxide in the reactor coolant by small hydrogen gas additions. Initial, very short term (~ 10 h and 4 days) in-reactor hydrogen injection tests were performed as early as 1979 and 1981 (Ref 109, 110). After a somewhat longer (6 weeks) hydrogen demonstration test at the Dresden-2 plant in 1982 (Ref 111), this plant became the first facility to initiate full-time operation on hydrogen injection, that is, hydrogen water chemistry (HWC). The test clearly demonstrated that the addition of hydrogen does indeed reduce the dissolved oxygen content as measured by electrochemical potential techniques plus oxygen analysis, and the beneficial effect of such environmental changes on IGSCC was verified by in-reactor constant extension rate tests at several BWRs (see Fig. 18a and Ref 58 and 112). Crack-growth data versus time and environment on precracked furnace-sensitized type 304 stainless steel obtained at several BWRs revealed that no significant crack extension occurs (Ref 113).

The laboratory hydrogen water chemistry materials program was characterized by an extensive test program (Ref 114). The testing

Fig. 37 BWR mean reactor water conductivity history

techniques utilized in the program included full-size pipe tests; fracture mechanics studies; electrochemical investigations; constant extension rate tests; straining electrode tests; constant load tests; bent beam tests; fatigue testing; cyclic crack-growth studies; general, galvanic, and crevice corrosion investigations; and corrosion oxide analysis. All of these laboratory studies clearly demonstrated that hydrogen water chemistry mitigates environmental cracking in, for example, BWR recirculation piping.

As shown in Fig. 38, the amount of hydrogen required to achieve this "protection potential" is nominally of the order of 1.0 to 1.5 ppm injected into the feedwater line. However, the kinetics of the H_2/O_2 recombination on the reactor structural surface is catalyzed by gamma radiation primarily in the downcomer region between the RPV wall and the core shroud. Consequently, the actual amount of hydrogen required for protection is plant-geometry specific and, in some cases, considerably more hydrogen is required, especially for protection of core internal structures such as the core shroud and top guides. The consequence of injecting an excessive amount of hydrogen is that volatile nitrogen species (e.g., N_2 , NH_3 , NO , NO_2) are formed due to homogeneous reduction reactions, and the radiation levels in the main steam line and turbine may increase by a factor of 4 to 5 due to the formation of ^{16}N via a neutron-proton (np) reaction on ^{16}O . As a consequence, hydrogen water chemistry is not effective in protecting reactor core internals without an unacceptable increase in radiation levels outside the reactor containment.

The current strategy for achieving a protection potential condition for all wetted reactor components (including the core internals) is to introduce a noble metal onto the material surface (Ref 115–117); this action effectively increases the exchange current densities for the $\text{H}_2/\text{H}_2\text{O}$ and $\text{O}_2/\text{H}_2\text{O}$ redox reactions and allows recombination of the O_2 and H_2 at much lower hydrogen addition levels. The noble metals favored are primarily platinum and rhodium that may be introduced either as (a) an alloying addition to the structural material, (b) a platinum-containing weld alloy that may be deposited as a cladding, or (c) as an aqueous additive to the feedwater line

Fig. 38 Variation of electrochemical corrosion potential (ECP) of stainless steel as function of feedwater hydrogen concentration

in the form of $\text{Na}_2\text{Pt}(\text{OH})_6$ and $\text{Na}_3\text{Rh}(\text{NO}_2)_6$. This latter process, known as noble metal chemical application (NMCA), has found wide application (Fig. 39) in that it effectively lowers the corrosion potential to below -230 mV (SHE) in core structures with less than 0.3 to 0.4 ppm H_2 addition to the feedwater line, that is, injection levels that do not lead to increases in the main steam line radiation level.

Summary of Current Situation and Commentary on the Future

It has been argued that because of defense-in-depth design and operating features, materials degradation issues such as SCC of core internals in current BWR designs do not increase significantly a plants' baseline core-damage frequency (CDF) or large energy release frequency (LERF) (Ref 118). However, there is no question that such failures have a marked negative impact on both the economy of plant operation (Table 2) and the public perception of nuclear reactor safety. Thus, the resolution of such problems is essential, especially with changes in the plants' licensing basis associated with, for example, life extension/license renewal and power uprates that may affect EAC susceptibility.

The early empirical understanding of the EAC phenomena (stress-corrosion cracking, corrosion fatigue) and the relative roles of the primary materials, environment, and stress input that define the degree of susceptibility was the basis of many of the EAC mitigation actions currently applied to BWRs. In the last 20 years, this capability has been complemented by a mechanisms-informed life-prediction methodology that accounts for the primary and secondary interactions between these inputs. This allows for a rapid analysis and understanding of the fundamental issues associated with new problems (e.g., cracking of core components) and a definition of appropriate mitigation and system control actions (e.g., development of cracking-resistant alloys and/or environmental modifications) that need to be implemented before costly damage ensues.

Fig. 39 Chronology of implementation of hydrogen water chemistry (HWC), and zinc injection, and noble metal chemical application (NMCA)

The challenges for the future will be governed by changes in operating and regulatory conditions. For instance, in the United States there is a steady movement toward regulations that are not only performance-based but also risk-informed. This development emphasizes decision-making that takes into account the relative importance of various maintenance, in-service inspection, procurement, and so forth activities in terms of their impact on plant safety (e.g., CDF, LERF) (Ref 119–123). To date, time-dependent materials degradation phenomena have not been included in the probabilistic risk assessments and the associated event- and fault-trees that address, for instance, either the accident initiation frequency or the reliability of components that play a role in subsequent accident mitigation. Thus, the near-term challenge in materials-degradation technology is to extend the current deterministic and mechanisms-informed understanding of the cracking phenomena to cover the uncertainties associated with the random crack-initiation processes, and the uncertainties associated with the propagation rate data and models.

A further operational driver that presents challenges is the constant desire for longer fuel cycles and the resultant increase in time between component inspections. This puts a premium on defining the kinetics of damage accumulation and the development of inspection techniques that have adequate resolution and probability of detection capabilities for the particular system at risk (Fig. 1).

Corrosion in Pressurized Water Reactors

Peter M. Scott and Pierre Combrade, Framatome ANP, an AREVA and Siemens company

A PRESSURIZED WATER REACTOR (PWR) is a type of nuclear reactor that uses ordinary light water for both coolant and neutron moderator. In a PWR, the primary coolant loop is pressurized so the water does not achieve bulk boiling, and steam generators are used to transmit heat to a secondary coolant, which is allowed to boil to produce steam either for ship propulsion or for electricity generation. In having this secondary loop, the PWR differs from the boiling water reactor (BWR), in which the primary coolant is allowed to boil in the reactor core and drive a turbine directly. More detailed information on BWRs can be found in the article "Corrosion in Boiling Water Reactors" in this Volume.

PWR Materials and Water Chemistry Characteristics

In order to review PWR materials corrosion issues, it is necessary to start with a description of the main materials and water chemistry characteristics of the primary and secondary water circuits and also to distinguish them carefully from those of BWRs. A schematic diagram of a typical PWR is shown in Fig. 1.

Materials Used. In the PWR, a high pressure of the order of 14 MPa (~2250 psi) is applied to the primary system to prevent general boiling of the primary coolant and ensure that the system is maintained liquid (unlike the BWR where water is allowed to boil as it is heated by the nuclear fuel). The PWR primary water is heated by passage over nuclear fuel that is clad with a zirconium alloy, cooled by its passage through the steam generator tubes, and then recirculated to the nuclear core. The interconnecting primary piping is made of austenitic stainless steel, typically type 304L, while the steam generator tubes are usually fabricated from a nickel-base alloy such as Alloy 600 and more recently, Alloy 690, or in some cases, Alloy 800. The primary pressure vessel is clad with a welded overlay of stainless steel as are the channel heads of the steam generators. The major surfaces in contact with the primary coolant are therefore mainly stainless steels, nickel-base alloys, and zirconium-base alloys.

Secondary-side coolant, on the outside of the steam generator tubes, boils to produce steam

that is used to turn the turbines and alternators in order to generate electricity. The pressure vessels of the steam generators are made from low-alloy steel, while the feed water and steam pipe work may be carbon or low-alloy steels, all of which are directly exposed to the secondary water or steam. The remaining components of the secondary circuit are the steam turbines, where various higher-strength low-alloy steels may be used, and the condensers whose tubes may be fabricated from copper-base alloys, titanium, or stainless steel, depending on the age of the plant and available cooling water (seawater, estuarine water, or river water).

A list of common structural steels used in PWRs for pressure vessels and piping is shown in Table 1. Typical austenitic, martensitic, and precipitation-hardened stainless steels are shown in Table 2, and nickel-base alloys in Table 3.

Water Chemistry Characteristics. Typical primary and secondary coolant conditions for PWRs are shown in Table 4. Hydrogen gas is

added to the primary circuit coolant at a concentration usually between 20 and 50 mL/kg at standard temperature and pressure (STP) (equivalent to 2–4 ppm by weight). This concentration is sufficient to ensure that any radiolytic decomposition products of water are rapidly scavenged by efficient ion-molecule and radical-molecule reactions. Consequently, corrosion potentials of all relevant structural materials are close to the hydrogen redox potential, as determined by the hydrogen partial pressure and the solution pH (Fig. 2) (Ref 1). By contrast, in direct cycle BWR systems, significant concentrations of oxygen and hydrogen peroxide are present as the end products of water radiolysis (which may be reduced by hydrogen additions in some BWR plants) and these fix the corrosion potential at significantly more positive values (Fig. 2). The other additives to the primary circuit of PWRs are boric acid, which participates with the control rods in moderating the nuclear chain reaction, and lithium hydroxide for pH control

Fig. 1 Basic flow diagram of a pressurized water reactor (PWR) nuclear power station

in the range 6.8 to 7.4 (at ~300 °C, or ~570 °F) (Ref 2). This value of the high-temperature pH on the primary side is designed to ensure minimum corrosion rates of the structural materials and minimum solubility of the protective spinel oxides that form on the metal surfaces, as discussed in more detail subsequently. For comparison, no chemical additives are made to BWR water other than hydrogen in some cases.

On the secondary side of PWRs, the objective of water chemistry control is also to ensure that corrosion rates are as low as possible, particularly of nonstainless materials in the feed train, as well as to minimize sludge (magnetite) transfer to heat transfer surfaces. This is achieved by a combination of a suitably alkaline pH (~9–10 as measured at room temperature) using ammonia and/or organic amines such as morpholine or ethanolamine together with hydrazine to reduce oxygen to negligible levels. If copper-base alloys are present in the secondary circuit, the upper limit allowed for pH with ammonia conditioning is 9.2 (at room temperature), which is less than that desired to reduce magnetite solubility to a minimum, and the use of an organic amine is then necessary. Hydrogen from general corrosion and thermal decomposition of hydrazine is

stripped preferentially to the steam phase and evacuated with any other noncondensable gases at the condenser. In addition, there is no evidence from in-plant measurements of any significant electrochemical influence of hydrazine itself on corrosion potentials (Ref 3). Consequently, corrosion potentials are somewhat more positive (~200 mV) on the secondary side compared with the primary side (Fig. 2). The most important secondary side corrosion problems are associated with hideout of secondary water impurities in occluded, superheated crevices next to the steam generator tubes where water circulation is restricted by a combination of geometry and sludge deposits.

General Corrosion, Crud Release, and Fouling

The first objective of water chemistry management is to ensure minimum loss of metal due to general corrosion by managing the solution pH, whether on the primary or secondary sides, to coincide as closely as possible with the

minimum solubility of spinel oxides such as magnetite. Nevertheless, some loss of metal thickness due to general corrosion does occur (between ~0.2 and 2 µm/yr, or 0.008 and 0.08 mils/yr) depending on the material (Ref 2, 4). While this has negligible influence on the load-bearing capacity of the pressure-retaining components, because of the large surface areas involved, the mass of material converted to oxide can be impressive, being potentially measured in tens of kilograms per year. This can have some important consequences for the operation of PWR systems.

On the primary side, release of cations into solution as well as particles of oxide allows them to pass through the nuclear core leading to transmutation of some elements into radioactive species. These activated species may then be transported out of the core and settle elsewhere, thus giving rise to radiation fields that can impede subsequent maintenance operations. On the secondary side, magnetite released from carbon steel surfaces is transported into the steam generator where it settles and/or precipitates on the steam generator tube surfaces, reducing thermal efficiency. Magnetite will also accumulate in low flow zones such as on the

tube sheet and in the interstices between the tubes and support plates (see Fig. 5 discussed later in this article) and enhance the phenomenon of hideout of impurity solutes that is responsible for serious corrosion problems on the secondary side of steam generator tubes.

Influence of Corrosion on Primary Circuit Radiation Fields

The primary source of radiation fields from PWR primary circuit components is from corrosion products generated on the surfaces

of iron-nickel alloys of the primary pressure boundary. The general corrosion that takes place on these surfaces releases dissolved metallic species, such as cations of iron, nickel, manganese, and cobalt, as well as colloidal oxide particles. Some of these metallic ions are deposited either by particle deposition or by precipitation on hot fuel element surfaces in the core where they are exposed to neutrons and may be activated by nuclear transmutation. The optimum pH for limiting corrosion product production and transport in the primary circuit has been found to be in the range 7.2 to 7.4 (at operating temperature).

Generation of Radioisotopes. The two primary radioactive isotopes generated in the core are ^{60}Co and ^{58}Co (Ref 5). Cobalt-60 arises as a result of neutron capture by naturally occurring ^{59}Co originating as an impurity (with nickel) in iron-nickel alloys used in reactor power plants or from stellites used as hardfacing materials in valves and elsewhere. The high neutron cross section of ^{59}Co and the high energy of the radioactive decay emissions from ^{60}Co cause it to predominate over radioisotopes formed from other elements that are present in higher concentrations. ^{58}Co is formed as a result of a neutron replacing a proton in the nucleus of ^{58}Ni , a naturally occurring isotope of nickel. Because the surface area of nickel-base alloys is usually large in PWRs due to the composition of the steam generator tubes, ^{58}Co is another very significant contributor to radiation fields.

Following the generation of radioisotopes from the deposits present on the surface of the fuel, various processes such as adsorption, ion exchange, dissolution, and erosion can cause the radioactive isotopes to be released from the fuel surface back into the reactor coolant. Transport with the reactor coolant allows some of these to be deposited later and incorporated into the growing oxide films on the surfaces of the reactor coolant system.

The main alloy constituents released by corrosion of the surfaces of the PWR primary circuit are iron and nickel. This fact, combined with the relatively reducing condition present in the primary coolant, results in deposits on the fuel that can be magnetite (in plants with Alloy 800 steam generator tubes), nickel oxide, metallic nickel, or nickel ferrite (in which nickel replaces one of the iron atoms in magnetite, Fe_3O_4 , by occupying a fraction of the tetrahedral lattice positions). As a result of the presence of both cobalt and nickel on the fuel, ^{58}Co and ^{60}Co are both significant sources of radiation in PWR systems. ^{58}Co , however, has a shorter half-life of 71 days and consequently is not retained from one refueling outage to the next, as is ^{60}Co , but is freshly generated from fuel cycle to cycle.

One of the most important regions in the PWR primary circuit for radiation control is in the channel heads of the steam generators where many maintenance and nondestructive examinations of steam generators take place.

Table 4 Typical pressurized water reactor (PWR) primary and secondary coolant chemistry conditions

Parameter	Primary water	Secondary water
Pressure, MPa (psi)	14.2 (2060)	5.4–7.2 (783–1044)
Temperature, °C (°F)	286–323 (547–613)	284–305 (543–581)

Consequently, this is a region where much of the radiation exposures associated with primary circuit maintenance occurs.

A second potential source of radioisotopes generated in nuclear power plants is within the fuel itself from nuclear fission and their decay products. These fission products are normally effectively contained within the zirconium-base cladding of each fuel rod although, occasionally, a few rods may develop pinholes or other types of penetrations, thereby permitting the release of fission products into the reactor coolant. Two of the major constituents of fission product radioisotopes are radioactive iodine and cesium.

Iodine, when released to the coolant, will predominantly shift toward volatile gaseous species and will be processed and monitored with the gases that are removed from the reactor coolant. Iodine generally makes an insignificant contribution to the total exposure experienced at nuclear power plants, although there have been occasional situations in which iodine, which has dissolved in the coolant at the time of shutdown, has delayed shutdown operations pending its removal from the coolant systems by ion exchange. Cesium, on the other hand, is readily soluble in reactor water, and therefore is removed from this water by the primary system demineralizers. Thus, cesium ends up in the radioactive waste, where it is processed and packaged on-site and shipped off-site for disposal. For each of these isotopes, and similarly for most fission product isotopes, due to their chemical behavior and/or their low concentration in the coolant water, they contribute relatively little to the radiation fields from components of the primary reactor coolant system.

Another potentially significant source of radioisotopes can arise as a result of failure of the stainless steel cladding of control rods containing silver-indium-cadmium neutron absorber, thus leading to the release of silver and its subsequent activation (Ref 6, 7). Such cladding failures can occur due to wear. Other cladding failures have been caused by undue swelling of the neutron absorber combined with loss of ductility in the cladding due to irradiation damage. The swelling occurs when a second phase is formed following the nuclear transformation reaction of indium into tin.

Radiation Control Techniques

The control of radiation fields has considerable influence on the cost of generation of nuclear power, and the radiation exposure experienced by the personnel who work in nuclear power plants is a key measure of the effectiveness of radiation field control measures (Ref 5). For PWRs, steam generator tube degradation and, more recently, upper head penetrations of the reactor pressure vessel have caused a significant increase in inspection and, in some cases, replacement of steam generators and/or upper heads, with a concomitant increase in personnel radiation exposure. Concurrent with

these problems has been the application of a number of techniques for reducing radiation exposure in plants. These have included techniques for reducing the radiation fields such as improved water chemistry control, materials selection, surface treatment, and decontamination (Ref 8–12).

Water Chemistry Control. In PWRs where precipitation and dissolution from fuel surfaces have been shown to be a significant influencing factor in radiation field buildup, the primary water pH can be controlled to reduce the amount of precipitate on the fuel surfaces. Lithium hydroxide (LiOH) concentration decreases as boric acid is reduced through the fuel cycle in order to maintain constant pH throughout most of the cycle. When the pH is high enough, in the region of 7.2 to 7.4 at operating temperature, the thermodynamics of the solubility of nickel ferrite are such that nickel ferrite will not precipitate on the fuel. This reduction in deposition on the fuel reduces the generation of cobalt isotopes and the subsequent buildup of radiation fields in the steam generator and elsewhere. Interest has also been shown in the use of small concentrations of soluble zinc (depleted in the ^{64}Zn isotope to <5% to avoid a zinc activation product) typically at a concentration ~5 to 10 ppb in the primary coolant. Zinc displaces cobalt and other cations from their tetrahedral crystallographic positions in the spinel oxides that form on stainless steels and nickel-base alloys. Cobalt is thus displaced into the primary coolant where it can then be removed by the primary cleanup system demineralizers. Oxide thicknesses and general corrosion rates are also significantly reduced by a factor of three or more by zinc addition (Ref 12). Another technique for reducing the inventory of activated elements in surface oxide films is to add sufficient hydrogen peroxide to eliminate dissolved hydrogen during the last stages of plant cooldown so that the redox potential becomes oxidizing. Cations including cobalt released into solution are then removed by the primary circuit demineralizers.

Materials Selection. High-cobalt alloys (Stellites) are present in most nuclear reactor systems, usually in valves, pumps, and control rod drive mechanisms. New materials containing low amounts of cobalt or no cobalt have been developed that are designed to serve the function of the high-cobalt alloys (Ref 11). Such replacements offer a significant opportunity for radiation field reduction from ^{60}Co together with the reduction of the cobalt source term in structural alloys, particularly nickel-base alloys used for steam generator tubing.

Surface Treatment. Many PWRs experience component replacement, and optimizing the surface condition of these new components can also help with radiation field control. Electropolishing has been shown to reduce the effective surface area by up to a factor of five on pipes and on steam generator channel head surfaces, for example, by removing surface asperities and creating a more uniform surface finish. Electropolishing also removes surface cold work and

produces surfaces that are more likely to develop a denser oxide film. Radiation exposures have also been reduced through the use of remote equipment, shielding, and extensive planning and training for high-exposure tasks.

Decontamination solvents that are effective in removing the radioisotopes from the oxide layers have also been developed. These solvents are used particularly when major maintenance and repair work is conducted on equipment that has very high radiation fields. Such decontamination can be combined with procedures such as chemistry control or electropolishing to reduce the subsequent radiation field buildups on these components (Ref 13).

Axial Offset Anomaly

The so-called “axial offset anomaly” is a severe perturbation of the axial neutron flux distribution in the nuclear fuel that is caused by the precipitation of boron-rich minerals on the surfaces of the fuel elements (Ref 14). It tends to be associated with fuel pins having a particularly high thermal flux and incipient local surface boiling so that the boron-rich precipitates tend to occur toward the top of the core. The problem has often been analyzed in terms of the thermodynamic conditions necessary to precipitate lithium metaborate, LiBO_2 , or even adsorption of nonionized boric acid. Recent chemical analyses of scrapings from fuel have, however, revealed more complex insoluble minerals such as bonaccordite (nickel boroferrite, Ni_2FeBO_5). Such observations emphasize the need for precise thermodynamic data so that the precipitation of such minerals can be predicted and avoided.

Secondary Circuit Corrosion and Fouling

Control of pH. The majority of PWR power plants control the pH of steam generator secondary water using all-volatile treatment (AVT), that is, pH control by ammonia (NH_3) or by amines such as morpholine ($\text{C}_4\text{H}_9\text{NO}$) and ethanolamine ($\text{C}_2\text{H}_7\text{NO}$). Many of the early plants used phosphates (Na_3PO_4) whose major advantage is its capacity to buffer against both acidic and basic impurity ingress, a protection that is only weakly afforded by amines. Volatile amines introduce no solids into the system, whereas the salts added in the phosphate method can accumulate and concentrate in superheated occluded areas. For this reason, use of phosphates has been discontinued in most plants and replaced by AVT following observations of caustic cracking of Alloy 600 steam generator tubes and/or wastage caused by concentrated phosphate phases (see the section “Tube Wastage” later in this article).

Control of Oxygen. Oxygen concentrations in power plant secondary feed water are controlled by adding scavenging chemicals (hydrazine, N_2H_4) and/or by mechanical means such

as the use of air ejectors on the deaerating section of condensers.

Control of Impurities. Chemical upsets in secondary water can be initiated by condenser tube failures; typical analyses of chemicals that can be introduced are shown in Table 5 (Ref 15). Air in-leakage rates of 2800 L/min (740 gal/min) can be experienced with severe condenser leaks, while a rate of one-tenth of that level has been common in the past. With 500 L/min (130 gal/min) in-leakage, the oxygen concentration in the secondary circuit condensate can increase to 30 ppm. Powder resin filters and deep bed demineralizers are two common condensate polishing systems used in some plants but, if not properly operated/regenerated, these systems can also become sources of ionic impurities.

Effect of Tube Fouling on Steam Pressure. As the PWR fleet has aged, problems have also been experienced with reduced steam pressure as a result of fouling of the secondary side of the tubes of PWR steam generators (Ref 10, 16–18). In a few extreme cases, even the broached holes in the tube support plates of more modern steam generators have become substantially blocked, giving rise to difficulties with secondary water level control. Considerable work has been undertaken to characterize the nature of the deposits responsible and the conditions under which they form. Remedial measures such as pressure pulse cleaning and chemical cleaning and the use of dispersants such as polyacrylic acid to avoid particle adhesion to steam generator tube surfaces have and are being investigated (Ref 17, 18).

Carbon and Low-Alloy Steel Corrosion due to Primary Water Leaks

Numerous incidents of primary water leakage have been reported since 1970 of which some have resulted in significant general corrosion or wastage of nearby carbon or low-alloy steel components (Ref 19). These incidents have been

attributed either to boric acid corrosion after concentration of the leaking primary water by evaporation or to the erosion-corrosion effects of high-velocity steam jets. The most serious case of boric acid corrosion was found in 2002 and had culminated in a pineapple-size hole being created in the low-alloy steel of the upper head of a PWR following a leak of primary water through stress-corrosion cracks in an Alloy 600 upper head penetration over a period of about five years.

Canopy seal cracks in the control rod drive mechanism housings above the reactor vessel head are a common source of primary water leaks onto the vessel head, although this has only rarely caused significant corrosion of the low-alloy steel. Another common cause of primary water leaks is from flanged joints ranging from the main vessel head to reactor pressure vessel seal to primary pump and valve flanges. In such cases, high-velocity steam jets have severely damaged and eventually severed high-strength low-alloy steels securing the flanges (Fig. 3) (Ref 20).

Many experimental studies have been carried out to reproduce the corrosion damage of carbon and low-alloy steels observed in PWRs due to primary water leaks (Ref 19–23). Simulations of in-service leaks of primary water using mockups are able to reproduce the high-velocity steam cutting phenomenon as well as the high corrosion rates under accumulated (moist) boric acid deposits. For example, a leak of primary water at 316 °C (601 °F) through a cracked stainless steel tube in a low-alloy steel plate produced a maximum corrosion rate of 55 mm/yr (2.17 in./yr) at the point where the leak escaped from the crevice between the tube and steel plate. Similarly, experiments have been carried out using jets of superheated steam from borated water at 316 °C (601 °F) directed at carbon steel surfaces. Corrosion rates of 15 to 25 mm/yr (0.6 to 1 in./yr) were observed just outside the zone directly impacted by the steam jet, whereas even higher rates were measured in the impact zone

where erosion doubtless contributed to metal loss.

Many experiments have also been conducted in aqueous solutions of boric acid as a function of concentration, pH, temperature, and flow velocity in order to quantify corrosion rates of carbon and low-alloy steels (Ref 19–21, 23). Corrosion rates in aerated boric acid solutions with concentrations similar to those of PWR primary water (<2000 ppm boron or 1.1% boric acid) do not exceed 5 mm/yr (0.2 in./yr). High corrosion rates in excess of 10 mm/yr (0.4 in./yr) and up to 120 mm/yr (4.7 in./yr) are observed only in the presence of aerated concentrated boric acid solutions or aerated moist boric acid pastes at intermediate temperatures around 100 °C (212 °F) as shown in Fig. 4 (Ref 23). In static concentrated boric acid solutions, the corrosion rate is observed to decrease rapidly over a period of a few hours, whereas in flowing solutions, such a decrease in the corrosion rate is not observed. This is probably due to the elimination of corrosion products as they are formed, thus avoiding saturation of the solution and consequent slowing of the corrosion kinetics. The weakness of these laboratory corrosion rate studies is that the high rates comparable with those observed in service are

reproduced only in aerated conditions, whereas aeration under the thick, moist deposits that form from primary water leaks in service seems rather unlikely.

PWR Primary Side Stress-Corrosion Cracking

There is little doubt that the most severe corrosion problem to affect PWRs is intergranular stress corrosion cracking (IGSCC) of Alloy 600 in PWR primary water. It has become a generic issue rivaling that of IGSCC of sensitized and/or cold-worked stainless steels in BWRs in terms of unanticipated outages and cost of repairs. Rather less-extensive or well known examples of stress corrosion cracking (SCC) in PWRs are those affecting austenitic stainless steels in occluded dead legs in PWR primary loops where it is sometimes difficult to guarantee adequate control of primary water chemistry or proper deoxygenation during plant startup. In addition, high-strength stainless steel and nickel-base alloy fasteners and springs are used extensively in PWR primary circuits, and some service failures of these items have also occurred.

Nickel-Base Alloys

Alloy 600, a nickel-base alloy containing 14 to 17% Cr and 6 to 10% Fe plus various minor elements (Table 3), was initially adopted for use in PWRs for steam generator tubes because of its excellent resistance to chloride cracking (from the secondary side) compared with stainless steel. It was also attractive for primary circuit components because of the closer similarity of its coefficient of thermal expansion to that of the low-alloy steel used to fabricate the reactor pressure vessel, pressurizer, and steam generator shells. A list of PWR components where Alloy 600 and similar nickel-base alloys are used in PWRs is given in Table 6.

The susceptibility of Alloy 600 to IGSCC in operational service in PWR primary water was first revealed in the early 1970s in tight U-bends

and in rolled, cold-worked transitions in diameter of steam generator tubes within and/or at the top of tube sheets (Ref 15). This then became a major cause of steam generator tube cracking in the 1980s, and later, premature steam generator retirement and replacement. The IGSCC of pressurizer nozzles and control rod drive mechanism (CRDM) penetrations in the upper heads of PWR reactor pressure vessels followed in the late 1980s and have continued for over a decade (Ref 1, 24). The CRDM penetration cracking appeared first in French PWRs in 1989, but only isolated cases were observed elsewhere until 2000. Apparently interdendritic, but in fact intergranular, SCC of the weld metals, Alloys 182 and 82 (Table 3), the former having a composition similar to Alloy 600, has also been observed recently in major primary circuit welds of several plants, often after very long periods in service ranging between 17 and 27 years (Ref 24). To these can be added the experience of extensive IGSCC in the γ' strengthened analogue of Alloy 600, Alloy X750, which is used for split pins attaching the CRDM guide tubes to the upper core plate. Even Alloy 718, a high-strength nickel-base alloy containing 17 to 21% Cr, which is normally considered a reliable high-strength material in PWR primary water use, has occasionally exhibited IGSCC (Ref 1).

The history of IGSCC in various PWR nickel-base alloy components is summarized

subsequently together with the methodologies developed to predict and mitigate cracking until, as sometimes is the case, replacement becomes unavoidable. The main remedy for susceptible Alloy 600 components is replacement, usually by Alloy 690 and its compatible weld metals, Alloys 152 and 52 (Table 3), which have proved to be resistant to IGSCC in PWR primary water both in severe laboratory tests and, to date, after up to 17 years in service.

Alloy 600 Steam Generator Tubes. Most PWR steam generators are of the "recirculating" type, although some are so-called "once-through" where all the secondary water entering the steam generator is transformed into steam; both are illustrated in Fig. 5. Most in-service primary side IGSCC has occurred in recirculating steam generators. An important difference between the two from the point of view of primary side IGSCC is that the once-through steam generators were subjected to a preservice stress relief of the whole steam generator at a temperature of about 610 °C (1130 °F). As well as promoting grain-boundary carbide precipitation in Alloy 600 (discussed in more detail subsequently), some grain-boundary chromium depletion (sensitization) also occurred. In one case, due to accidental ingress of thiosulfate, this led to extensive intergranular attack (IGA) of the sensitized tubes of a plant with once-through steam generators. In general, however,

Table 6 Pressurized water reactor (PWR) components fabricated from nickel-base alloys

PWR components	Nickel-base alloy grades used
Steam generator tubes	600 MA and TT, 690 TT and 800
Steam generator divider plates	600 and 690
Upper head penetrations	600 and 690 (except in Germany)
Lower head penetrations	600
Core supports	600
Pressurizer nozzles	600 and 690
Safe ends	600
Weld metal deposits	82, 182, 52, and 152
Fuel grid and hold-down springs	718
Split pins	X750

Fig. 5 Sketches of (a) recirculating and (b) once-through type PWR steam generators.

the lower-strength and grain-boundary carbide precipitation in once-through steam generator tubes has proved to be advantageous for resistance to IGSCC on the primary side, despite the sensitization, although even these are now being replaced after typically 20 to 25 years service (Ref 25).

Primary side IGSCC of Alloy 600 steam generator tubing evolved from a laboratory prediction during the 1950s and 1960s to a major degradation mechanism from the 1970s onward. As early as 1957, laboratory studies of cracking of high-nickel alloys in high-purity water at 350 °C (660 °F) were reported (Ref 26), although at that time the importance of the corrosion potential as fixed by the hydrogen partial pressure was not understood. During the following years, numerous laboratory tests were performed in different environments to duplicate and explain these observations. In 1971, the first confirmed primary side cracking of hot-leg roll transition regions at the tube sheet and suspected primary cracking in tight first row U-bends of recirculating steam generators occurred (Ref 27). Leakage at U-bends was experienced in the Obrigheim (Germany) steam generators after only 2 years of operation.

From the mid-1980s to the present day, cracking of Alloy 600 tubes from the primary side became a problem of great importance, as shown as "SCC (ID)" in Fig. 6 (Ref 28). Cracking occurred both in the tight U-bends, mainly on the inner two rows at the apex and at the tangent points with the straight sections, and in the tube sheet at the transition expansion or roll expansion regions of recirculating steam generators. The latter has been responsible for premature steam generator replacement at many plants.

The first roll transitions experiencing IGSCC were located on the hot-leg side where the temperature is typically around 320 °C (610 °F) and is 30 to 40 °C (55 to 70 °F) hotter than the cold-leg inlet at 280 °C (535 °F). Thus, it was clear that temperature had a significant influence on IGSCC initiation, indicating a thermally activated process whose temperature dependence could be fitted to the Arrhenius equation. The apparent activation energy so derived is rather high (~180 kJ/mole for crack initiation) so that a typical temperature difference of 30 °C (55 °F) between hot and cold legs could easily account for a factor of four to five increase in the time to the onset of cracking. Thus, reduction of hot-leg temperature has been one possible mitigating action that has been used. Hot-leg temperature reductions from 4 to even 10 °C (7 to 18 °F) have been applied without necessarily always losing on maximum power output depending on the margins available in the turbine.

The magnitude of the tensile stresses, particularly residual stress from fabrication, also has a major impact on the initiation time for IGSCC so that only the most highly strained regions of steam generator tubing (that is, row one and two U-bends, roll transition regions, expanded regions, and dented areas) have exhibited IGSCC. From laboratory studies of susceptible materials, a threshold stress below which cracking will not occur of ~250 MPa (35 ksi) has been determined, and time-to-failure has been observed to depend approximately on stress⁻⁴ (Ref 1). Consequently, several stress mitigation techniques have been developed such as local stress relief of first and second row U-bends by resistance or induction heating, and shot peening or rotopeening to induce

compressive stresses on the internal surface of roll transitions (Ref 29, 30). While peening helps to prevent initiation of new cracks, it cannot prevent growth of existing cracks whose depths are greater than that of the induced compressive layer, typically 100 to 200 µm (0.004 to 0.008 in.). Thus, peening has been most effective when most tubes have either no cracks or only very small ones, i.e. when practiced before service or very early in life (Ref 30, 31).

Material susceptibility, in combination with the aforementioned factors, is also a major factor affecting the occurrence of IGSCC. Most IGSCC has occurred in mill-annealed tubing. However, it is important to emphasize that there is not a single product called "mill-annealed" Alloy 600 tubing because each tubing manufacturer has employed different production processes. Whereas some mill-annealed tubing has not experienced any IGSCC over extended periods of operation, in other cases it has occurred after only 1 to 2 years of service, particularly at roll transitions. This variability of IGSCC response is even seen between heats from the same manufacturer in the same steam generator, as shown in Fig. 7 (Ref 1). It can be seen in Fig. 7 that susceptibility to IGSCC of the heats of Alloy 600 fits approximately a log-normal distribution so that a rather small fraction of Alloy 600 heats may be responsible for a disproportionately high number of tubes affected by primary side IGSCC. The reasons for such variability are only partly understood.

This microstructural aspect of IGSCC has been observed to be strongly affected by the final mill-annealing temperature and whether precipitation of grain-boundary carbides occurs during this treatment. The most susceptible microstructures are those produced by low mill-annealing temperatures, typically around 980 °C (1800 °F), that produce fine grain sizes (ASTM 9 to 11), copious quantities of intragranular carbides, and, usually, few if any intergranular carbides (Ref 32, 33). Higher mill-annealing temperatures in the range of 1040 to 1070 °C (1900 to 1960 °F) avoid excessive grain growth and leave enough dissolved carbon so that intergranular carbide precipitation occurs more readily during cooling. A further development of this idea was to thermally treat the tubing after mill annealing for ~15 h at 705 °C (1300 °F), which enhances intergranular carbide precipitation and provides enough time for the grain-boundary chromium concentration to recover and avoid sensitization (Ref 33). The beneficial influence of grain-boundary chromium carbides on primary side IGSCC resistance has been extensively evaluated. It has been demonstrated that grain-boundary carbides improve primary-side IGSCC resistance with or without grain-boundary chromium depletion, as also deduced from the generally good operating experience of Alloy 600 tubing of once-through steam generators (Ref 25, 32, 33). However, even thermally treated Alloy 600 tubing has cracked in service, although much less frequently than mill-annealed Alloy 600.

Fig. 6 Worldwide causes of steam generator tube plugging. SCC (ID), primary side SCC; SCC/IGA, outside surface SCC/IGA. Source: Ref 28

This has usually been attributed to a failure of the thermal treatment to produce the desired intergranular carbide microstructure either due to insufficient carbon or factors such as tube straightening prior to thermal treatment, which have favored carbide precipitation on dislocations instead of grain boundaries.

Steam generator tubes with IGSCC detectable by nondestructive testing have usually been preventively plugged either to avoid leakage or before the crack length reaches some pre-defined conservative fraction of the critical size for ductile rupture. Sleeving has sometimes been deployed as a repair method in operating PWRs to avoid plugging and maintain the affected tubes in service. The sleeves bridge the damaged area and are attached to sound material beyond the damage. The ends of the sleeves may be expanded hydraulically or explosively and are in most cases sealed by rolling, welding, or brazing (Ref 15).

More recent steam generators have been fabricated using Alloy 690 tubes thermally treated for 5 h at 715 °C (1320 °F). As well as being highly resistant in severe laboratory tests to IGSCC in PWR primary water compared with either mill-annealed or thermally treated Alloy 600, the lead steam generators with thermally treated Alloy 690 tube bundles have at the time of writing in early 2004 about 15 years of service with no known tube failures (Ref 34).

Thick Section Alloy 600 Components. Thick section, forged, Alloy 600 components started to crack in the mid 1980s starting with pressurizer nozzles (Ref 1, 35). In France, for example, all pressurizer nozzles were replaced with stainless steel. In 1989, the first cracking

of Alloy 600 upper head CRDM nozzles occurred at the Bugey 2 plant in France. At first, it appeared as though this might be a special case because of the combination of a stress concentration due to a counter bore in the nozzles just below the level of the J-groove seal weld with the upper head as well as a relatively high operating temperature that was believed to be close to that of the hot leg in this first-generation French plant. However, the problem spread during the 1990s to CRDM nozzles in other plants with no counter bore, or with a tapered lower section to the CRDM nozzle, and in upper heads where the temperature was the same as the inlet cold-leg temperature (Ref 36, 37).

Three common features of the cracking of upper head CRDM nozzles were the presence of a significant cold-worked layer due to machining or grinding on the internal bore, some distortion or ovalization induced by the fabrication of the J-groove seal welds, and a tendency to occur more frequently in the outer setup circles where the angles between the vertical CRDM nozzle and the domed upper head were greatest. The combination of these three features plus the fact that the upper head is stress relieved before the CRDM nozzles are welded in place pointed to high residual stresses being responsible for these premature failures.

Although the generic problem of Alloy 600 CRDM nozzle cracking appeared first in France, only sporadic instances of similar cracking were observed in other countries until the beginning of the twenty-first century when numerous other incidents were reported. In some cases where cracking was allowed to develop to the point of leaking primary water into the crevice between

the CRDM nozzle and the upper head, circumferential cracks initiated on the outer surface of the CRDM nozzle at the root of the J-groove seal weld (Ref 38). This had been observed in 1989 at Bugey 2 but only to a minor extent. No further leaks of primary water due to CRDM nozzle cracking have occurred in France because of an inspection regime adopted to avoid them and a decision taken to replace all upper heads using thermally treated Alloy 690 CRDM nozzles (Ref 36, 37). At the time of writing in early 2004, over 80% of upper heads had been replaced in French PWRs, and the same strategy is slowly being adopted elsewhere as the costs of repeat inspections makes any other policy uneconomic.

Nickel Base Weld Metals. The history of IGSCC in Alloy 600 and similar nickel-base alloys has taken yet another twist in recent years with the discovery of cracked Alloy 182 welds in several PWRs around the world (Ref 38, 39). This has occurred on the primary water side of J-groove welds that seal the CRDM nozzles in the upper head and also in a few cases in the safe-end welds of the reactor pressure vessel or pressurizer. Cracking seems to be significantly exacerbated by the presence of weld repairs made during fabrication, usually to eliminate indications due to hot cracking, thus again emphasizing the role of high residual stress in the failures observed to date. The cracking has often been described as interdendritic, but recent work shows that it is in fact intergranular (Ref 40). Incubation periods seem to be very long, of the order of 20 years, which certainly poses some interesting questions as to the mechanism of SCC.

Life Prediction of Alloy 600 Components. In spite of the improvements available for new plants or for component replacement, many Alloy 600 components, either mill annealed, thermally treated, or forged, remain in service. While most show no sign of cracking in service, it is important to have some tools to assess component life and predict when replacement may become necessary. Prediction methodologies were first developed for steam generator tubes and later extended to pressurizers and upper head CRDM penetrations. Both deterministic and probabilistic methods have been developed and are summarized next (Ref 41, 42).

Modeling of Alloy 600 component life is often based on the following empirical equation:

$$t_f = C \frac{\sigma^{-4}}{I_m} \exp\left(\frac{E}{RT}\right) \quad (\text{Eq 1})$$

where t_f is the failure time (hours), C is a constant, σ is the applied stress (MPa), I_m is a material susceptibility index (see, Table 7), E is the apparent activation energy (cal/mole or J/mole), R is the universal gas constant (1.987 cal/mole/K or 8.314 J/mole/K), and T is the absolute temperature (in degrees K).

Despite the scatter observed in determinations of apparent activation energy, there is a reasonable consensus that a value of 180 kJ/mole (44 kcal/mole) is adequate for component life

Fig. 7 Distribution of heats of Alloy 600 by susceptibility to intergranular stress-corrosion cracking (IGSCC) on the primary side of steam generator tube roll transitions in three steam generators (SG1, SG2, SG3) of the same plant. Source: Ref 1

estimations and 130 kJ/mole (30 kcal/mole) for crack growth estimations. Establishing the stress including residual fabrication stress on a given component is not trivial, but well tried and proven approaches based on finite element stress analysis or experimental techniques applied to mockups are available. However, dealing with material variability in susceptibility to IGSCC is not so straightforward and, in the case of classification of the susceptibility of CRDM nozzle cracking in U.S. PWRs, material variability has not been taken into account. The strategy for inspection and eventual replacement of upper heads in U.S. plants has been based on an evaluation of equivalent damage years determined only by the Arrhenius part of Eq 1 from the operating time and temperature, as shown in Fig. 8 (Ref 38). Nevertheless, as can be seen in Fig. 8, this approach has apparently correctly identified the plants most at risk from IGSCC of Alloy 600 CRDM nozzles.

A different approach was taken in France to address the same problem. It was observed that even after accounting for differences in stress and temperature, the variability attributed to material response could be considerable; up to a factor of 20 based on French PWR operating

experience. One method to account for variability in material resistance to IGSCC has been based on a system of material indices, I_m , in Eq 1 (Ref 43–46). At its simplest, with no direct information about IGSCC susceptibility of individual heats, the guidelines given in Table 7 were adopted. They were based on observations of minimum times-to-failure of plant components or, in cases where no service failures had been observed, of laboratory specimens in accelerated tests of representative plant materials. The constant C in Eq 1 was adjusted so that an index of unity corresponds to a minimum failure time of 10,000 h at a temperature of 325 °C (615 °F) and an applied stress of 450 MPa (65 ksi), as observed in practice in plant and in laboratory tests. In addition, temperature (I_0) and stress (I_σ) indices were defined relative to the reference conditions of 325 °C (615 °F) and 450 MPa (65 ksi) consistent with Eq 1 as:

$$I_0 = \exp \left[\left(\frac{-E}{R} \right) \left(\frac{1}{T} - \frac{1}{598} \right) \right] \quad (\text{Eq 2})$$

$$I_\sigma = \left(\frac{\sigma}{450} \right)^4$$

Table 7 Minimum failure times for IGSCC of Alloy 600 components in pressurized water reactor (PWR) primary circuits

Alloy 600 parts	Material index (I_m)	Stress index (I_σ)	Temperature index (I_0)	Overall index product	Time, h	Observation(a)
Hydraulic expansion	0.2	0.4	1	0.08	80,000	NC

Thus

$$t_f = \frac{10,000}{I_m \cdot I_0 \cdot I_\sigma} \quad (\text{Eq 3})$$

In this way, the minimum time to cracking of each generic Alloy 600 primary circuit component was assessed after determining its operating temperature and stress. The results for different generic components of PWR primary circuits are shown in Table 7. Appropriate surveillance strategies were then established.

The quantification of variability of Alloy 600 heat susceptibility to IGSCC has been developed further to assess cracking encountered in the upper head CRDM nozzles of French PWRs and extended to other large Alloy 600 primary circuit components (Ref 42–47). The assessment of heat susceptibility is based on the premise that the distribution of carbides on the grain boundaries and within the grains is the principal parameter controlling susceptibility to IGSCC. Because the carbide microstructure cannot be easily determined by sampling components in service, the approach taken was to study experimentally the microstructure of as many product forms and processing conditions as possible and to categorize them into classes. Three main types of microstructure were recognized and related to the carbon concentration, thermal treatment, especially the temperature at the end of forging or rolling operations, and yield strength after hot working:

- Class A with mainly intergranular carbide precipitates
- Class B recrystallized with carbides mainly on a prior grain-boundary network
- Class C recrystallized with randomized intragranular carbides as well as carbides on prior grain boundaries

These classes were then linked to their IGSCC resistance (i.e., material susceptibility index) as determined from operating experience in the case of upper head penetrations or in accelerated laboratory tests mainly at 360 °C (680 °F). As more product forms associated with other Alloy 600 primary circuit components such as reactor pressure vessel bottom head

Fig. 8 Equivalent damage years (EDY) for the upper head control rod drive mechanism (CRDM) nozzles of U.S. PWRs in Sept 2002. ISI, in-service inspection. Source: Ref 38

penetrations, steam generator partition plates, and core supports (M-supports) were tested, it became necessary to increase the number of classes of microstructures to seven, for example, to include the influence of twin boundaries, heterogeneous grain sizes, and presence of both intergranular and intragranular carbides (Ref 42, 46).

Inevitably, such an approach to assessing IGSCC susceptibility reveals significant scatter in the susceptibility indices for different heats about the mean associated with each class. That uncertainty has been incorporated into life estimations, as described subsequently. However, practical assessments of the risk of IGSCC of primary circuit components fabricated from Alloy 600 have generally used the best estimate of the susceptibility index based on fabrication data coupled with conservative values of operating stress and best estimates of operating temperature. This method has been used to define appropriate surveillance and maintenance strategies for different generic classes of components in primary circuits of French PWRs.

Application of the Weibull distribution to quantify the dispersion in stress corrosion data is well established and has been successfully applied to IGSCC in Alloy 600 steam generator tubes and upper head penetrations (Ref 41, 42). The dispersion in times to observe detectable cracks arises from the inherent variability in susceptibility of materials to SCC and, in the case of plant components, to uncertainty in the precise operating stress and temperature. The most useful form of the Weibull distribution is the linear transform of the cumulative distribution function:

$$\ln \ln \left(\frac{1}{1-F(t)} \right) = \beta \ln(t-t_0) - \beta \ln(\eta - t_0) \quad (\text{Eq 4})$$

where $F(t)$ is the fraction of components failed, t is the failure time (hours or years), t_0 is the location parameter or origin of the distribution (hours or years), η is the characteristic life or scale parameter (hours or years), and β is the shape parameter and slope of the linear transform.

The Weibull distribution can be fitted to the early observations of IGSCC as a function of operating time and provides an effective tool for predicting the future development of cracking so that informed inspection and repair plans can be formulated (Ref 41). This approach has also been adapted to French operating experience of IGSCC in the roll transitions of steam generator tubes and incorporating the method of material indices described earlier (Ref 42). For the reference conditions, material index, $I_m = 1$, a stress of 450 MPa (65 ksi), and a temperature of 325 °C (615 °F), the appropriate Weibull distribution parameters were determined to be:

$$\begin{aligned} \beta &= 1.5 & \eta &= 100,000 \text{ h} \\ t_0 &= 0.1 \eta & &= 10,000 \end{aligned}$$

The slope β is significantly lower than values deduced from U.S. operating experience (Ref 41) probably because the latter did not incorporate an analysis of t_0 .

For other Alloy 600 components subject to IGSCC for which estimates of material susceptibility indices were available (e.g., Table 7), the characteristic life and origin of the distribution were easily calculated for each heat using Eq 1 or 3 and the estimated values of operating temperature and stress (Ref 42). The Weibull shape parameter is more difficult to determine, but after examining IGSCC data for other Alloy 600 components and laboratory specimens, the main influence was observed to come from the applied stress, for which an empirical equation was derived:

$$\beta = 0.75 \left(\frac{\sigma - 250}{100} \right) \quad (\text{Eq 5})$$

Thus, as the stress increases, the slope β increases and the scatter about the mean life decreases, as might be expected.

In order to improve further the stochastic approach to predicting IGSCC in the context

of upper head penetration cracking encountered in French PWRs, the inherent dispersion in the input parameters of stress, temperature, activation energy, and material susceptibility index was taken into account. It was clearly not physically realistic to treat heat-to-heat variability as a quantized phenomenon as implied by Table 7, and a log-normal distribution of material susceptibility indices was chosen in accordance with the populations of heats assessed in each class A, B, C, and so forth. The Monte Carlo simulation technique of randomly sampling distributions of the input parameters in Eq 1 to determine a distribution of failure times was adopted, as illustrated in Fig. 9 (Ref 42).

An example of the results using the Monte Carlo approach outlined in Fig. 9 is shown in Fig. 10 in the form of a Weibull distribution comparing the results of these simulations with the inspection results for upper head penetrations in each susceptibility class of Alloy 600 (Ref 42). When the Monte Carlo simulations are repeated many times, the dispersion in the resulting Weibull distribution of failure times is relatively small because the number of penetrations considered for each PWR plant series is over 1000.

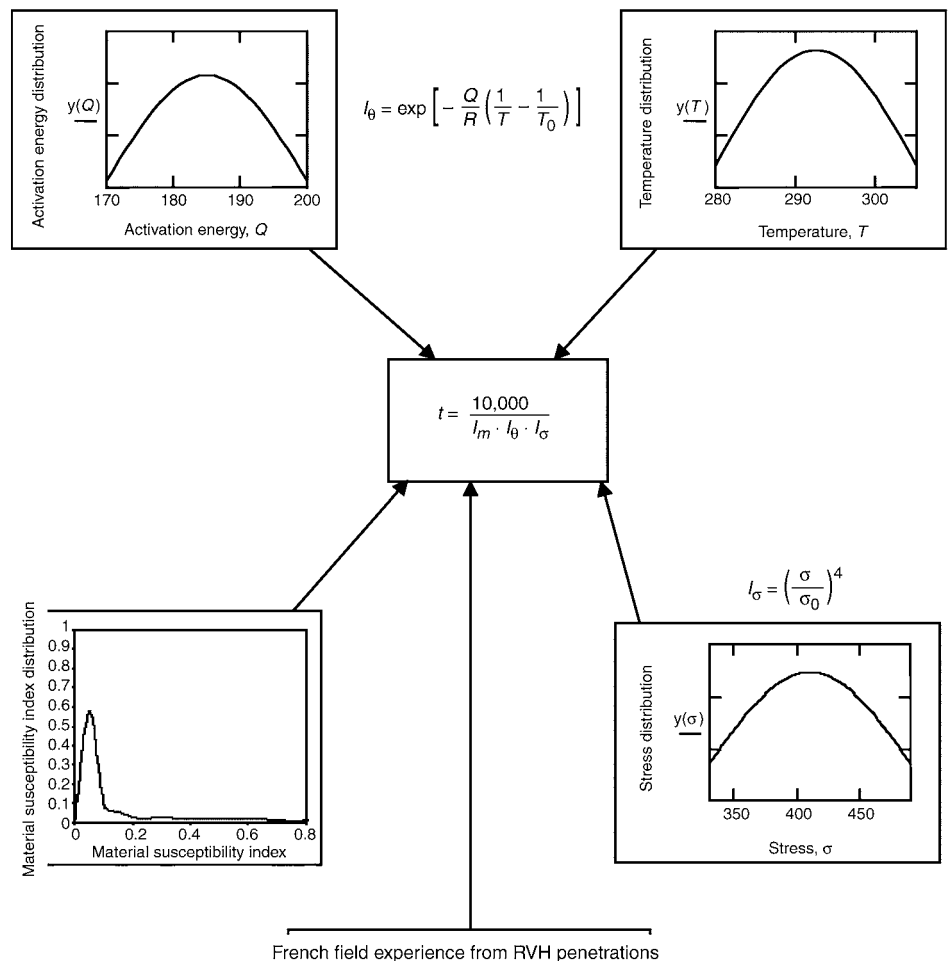

Fig. 9 Illustration of Monte Carlo simulation of upper head penetration cracking. RVH, reactor vessel head. See text for an explanation of other symbols. Source: Ref 42

Thus, the progression of the problem for each design series of PWRs has relatively little inherent uncertainty. On the other hand, if the problem is considered on a plant-by-plant basis, then although the numbers of penetrations in each class of material susceptibility considerably affect the risk of IGSCC occurring, the statistical uncertainty in predictions of the proportion that will crack in a given operating time is much greater because there are less than a hundred CRDM penetrations per upper head. For a given upper head, this statistical uncertainty in the number of cracked penetrations can be of the order of ± 1 to ± 5 on the mean prediction. This uncertainty is easily demonstrated and quantified in a probabilistic sense using the Monte Carlo simulation technique.

It is well known among stress corrosion specialists that surface finish can have a dramatic influence on component susceptibility to cracking in service, but quantifying the effect has not been so obvious until recently (Ref 35, 43, 45, 46). One important consequence of the experience of upper head penetration IGSCC experienced in French PWRs has been a careful characterization and measurement of the thicknesses of cold-worked layers and residual stresses left by different machining techniques as well as a quantitative framework for understanding what is of concern and what is not.

It is observed experimentally that the lifetime to failure by IGSCC of Alloy 600 specimens in PWR primary water depends on the extent of cold work in the surface layer and on its thickness. Most machining methods leave a cold-worked layer on the surface that is normally in compression. If this layer is then placed in tension due to an applied stress exceeding the yield stress of the more ductile substrate, then

very high tensile stresses easily up to 1000 MPa (145 ksi) can be generated in the cold-worked layer (Ref 35, 43). Whether this has much effect on the time to failure by IGSCC then depends on the layer thickness. If the compressive strain in the surface cold-worked layer is not reversed, then of course a favorable effect on IGSCC resistance is observed. Thus, the practical problem with remedies such as shot peening, for example, is to ensure that the underlying more ductile substrate is never strained beyond its yield point.

The interpretation and quantification of the influence of surface layers on IGSCC in Alloy 600 has been based on three principles (Ref 43). First, crack growth rates are increased by cold work when the material is loaded above its yield strength. Secondly, the evolution of cracking is characterized by three distinct phases: an incubation period, a slow crack growth period and (when $K_I > K_{ISCC}$) a rapid crack growth period, the difference in growth rates being about an order of magnitude. The third principle used to quantify the effect of cold-worked surface layers on IGSCC life is that both the slow and fast phases of crack growth rate depend primarily on the crack tip strain rate.

The effect of a cold-worked layer with high residual stress caused by yielding of the more ductile substrate on the slow to fast growth rate transition is illustrated in Fig. 11. If the cold-worked surface layer is thin and the transition in growth rates occurs in the underlying material unaffected by cold work, then a smaller effect on lifetime is observed; cold work increases the crack growth rate only over the short distance the crack travels through the cold-worked layer. If the cold-worked and highly stressed layer is thick enough so that the transition in growth rates

occurs within it, then the crack length associated with the transition will be much shorter because of the higher stress, and the lifetime to failure will be significantly reduced.

The detailed mathematical treatment of crack growth based on a strain rate dependent model to calculate failure times with various assumptions about the extent and depth of cold work is complex (Ref 43). Nevertheless, the overall effect of surface cold work on IGSCC life that results from this treatment can be presented simply in terms of an effective stress that would induce the same crack initiation time (to reach the rapid crack growth phase) from an electro-polished surface compared with the same material with a cold-worked surface layer. Figure 12 shows the effect of thickness of the cold-worked layer with a surface tensile stress of 1000 MPa (145 ksi) overlying a substrate with a yield stress of 300 MPa (44 ksi). Taking one example from Fig. 12, for an applied stress of 500 MPa (73 ksi) and a 200 μm (0.008 in.) thick cold-worked layer characteristic of heavy machining or grinding, the equivalent stress to give the same failure time without the cold-worked layer would be 900 MPa (131 ksi); i.e., a reduction in life due to the cold-worked layer

by a factor of $(900/500)^4$ is anticipated, which is equivalent to an order of magnitude.

Crack Propagation of Alloy 600 Components. Once a stress corrosion crack has been detected by nondestructive examination in a PWR primary circuit component, an essential step in the justification of structural integrity and further operation without repair or replacement of the affected component is an assessment of crack growth during the next few operating cycles. Practical approaches to assessing crack growth by IGSCC in Alloy 600 components have relied on empirical measurements of crack growth rates as a function of crack tip stress intensity, K_I , rather than the strain rate based relationships referred to previously that are much more difficult to use. A compilation published in 1999 compared laboratory data with field measurements on upper head penetrations of French 900 and 1300 MW PWRs (Ref 48).

There is fairly general agreement that the most appropriate form of the crack growth equation for IGSCC of Alloy 600 in PWR primary water is (Ref 49):

$$\frac{da}{dt} = C(K_I - 9)^n \quad (K_I \text{ in MPa}\sqrt{\text{m}}) \quad (\text{Eq 6})$$

The values of the coefficient C and exponent n for given practical circumstances vary among different publications, but there is a reasonable consensus that the apparent or effective activation energy to be used for adjusting the coefficient C for temperature is ~ 130 kJ/mole. Cracking events in Alloy 600 upper head penetrations and weld deposits of Alloys 82 and 182 have once again focused attention on the appropriate values of the coefficients to use for the evaluation of indications found by non-destructive examinations.

Other variables that are known to influence the rate of crack growth in Alloy 600 are cold work, hydrogen overpressure, and possibly pH or lithium hydroxide concentration. Cold work can easily affect the value of the coefficient C by as much as an order of magnitude. Hydrogen overpressure effects are also significant (Ref 50). However, this effect has not been explicitly included in crack growth assessment equations to date, probably because the hydrogen concentration in PWR primary water is controlled within a relatively narrow range. Concerning the possible influence of pH or lithium concentration in PWR primary water on crack growth kinetics, the effect is small within the range of pH or lithium concentrations permitted by the PWR primary water specification (Ref 1, 42).

Summary of Alloy 600 Laboratory Investigations. The generic IGSCC of the nickel-base Alloy 600 and its high-strength analogue, Alloy X750, in PWR primary water has been extensively studied. Despite considerable experimental efforts, no consensus exists as to the nature of the cracking mechanism (Ref 51) and both life modeling and remedial measures have relied on empirical, phenomenological correlations, as described earlier. The essential

phenomenological features of primary water IGSCC of Alloy 600 are:

- The profound influence of hydrogen partial pressure (or corrosion potential) and observation of a worst case centered on corrosion potentials near the Ni/NiO equilibrium (Fig. 2)
- The apparently continuous mechanism of failure between 300 °C (570 °F) subcooled water and 400 °C (750 °F) superheated steam
- The high and variable apparent activation energy typically 180 kJ/mole but with a scatter band of 80 to 220 kJ/mole
- The influence of carbon content and microstructure, particularly the favorable influence of grain-boundary carbides and undesirable effect of cold work
- The high stress exponent of ≈ 4 for lifetime to failure

The mechanism of IGSCC of Alloy 600 in PWR primary water is the subject of intense debate in the technical literature, and it is difficult to find any consensus even on issues as basic as whether cracks advance by an oxidation process at the crack tip or due to embrittlement by hydrogen discharged from the matching cathodic reaction (Ref 51). The magnitude of the activation energy is perhaps one of the most difficult parameters to explain. Physical support for the fourth power dependency on applied stress comes mainly from studies of grain-boundary sliding observed during primary creep in Alloy 600 at temperatures between 325 and 360 °C (615 and 680 °F) (Ref 43, 52). However, the same dependency on stress can also be easily demonstrated if grain-boundary oxidation controlled by parabolic kinetics to some critical depth is required for crack initiation. Grain-boundary sliding rates are observed to depend on grain-boundary carbide coverage, greater coverage being associated with slower grain-boundary sliding rates and higher resistance to IGSCC, as observed in practice. Nevertheless, although grain-boundary carbide morphology is a major reason for heat to heat variability in susceptibility to IGSCC of Alloy 600 in PWR primary water, it is clear that other as yet unidentified metallurgical factors also play a role.

High-Strength Nickel-Base Alloys

Improvements have been made to Alloy X750 for PWR primary water service by increasing the annealing temperature and resultant grain size and by the adoption of single-step aging at 704 °C (1299 °F) for 20 h. Although the main goal of the aging heat treatment is to precipitate the strengthening phase γ' , $\text{Ni}_3(\text{Ti, Al})$, an added advantage of these heat treatment conditions is a fine, dense M_{23}C_6 carbide distribution at grain boundaries (Ref 53).

The need to pay attention to the surface condition of components, particularly with respect to cold work and residual stress, has been emphasized earlier. The example of Alloy X 750

is a case in point where the atmosphere used during aging heat treatment was found to influence initiation times for IGSCC in PWR primary water (Ref 53). This was due to oxidation of surface layers that had to be removed by machining after heat treatment in order to ensure optimum performance in service. A more recent similar example is with Alloy 718, a normally highly reliable high-strength alloy for use in PWR primary water. Some studies in the literature have implicated the formation of δ phase during thermal aging as having an aggravating influence on IGSCC susceptibility (Ref 54). Others have not observed a major effect of δ phase on product performance and indeed is a necessary feature to avoid excessive grain growth during solution treatment prior to aging (Ref 1). By comparison, oxidation of the surface during product rolling can have a severe adverse influence on IGSCC initiation in PWR primary water. The reason is not hard to miss in micrographs where intergranular oxidation during product rolling provided a precursor intergranular crack when stressed prior to exposure to PWR primary water. For optimum IGSCC resistance in plant, it was essential to remove the layer affected by the furnace atmosphere, as observed previously for Alloy X750.

Low-Strength Austenitic Stainless Steels

Type 304 and 316 stainless steels are the main materials used for the pressure boundary and other components of PWR primary circuits. Operating experience with these materials since the mid-1960s has generally been excellent. When stress corrosion failures have occurred, they have in most, if not all cases, been due to internal or external surface contamination by chlorides or to out-of-specification chemistry in dead legs or other occluded volumes where primary water chemistry control can be difficult (such as the transient presence of oxygen for significant periods) (Ref 1). Excessive cold work, with the attendant risk of martensite formation in type 304 stainless steel, has also been a contributing factor in some cases. Although low-carbon grades of types 304 and 316 stainless steels have often been used to minimize the risk of sensitization (by grain-boundary chromium depletion) of weld heat-affected zones, there is little doubt that such sensitized materials exist in considerable quantities in many older PWRs. Nevertheless, practical experience shows that deoxygenated, hydrogenated PWR primary water does not cause stress corrosion in such sensitized materials, in contrast to BWR experience with oxygenated water.

The exceptions to this excellent record, aside from inadvertent surface contamination, are associated with the difficulty in maintaining the low concentrations of impurities (<150 ppb Cl^- , for example) required by the primary water

specification in areas where water circulation is restricted. In addition, dead legs can trap air bubbles during refueling and maintenance that may then be difficult to eliminate when refilling and pressurizing the primary circuit. Temperatures in such locations are also usually much lower than those in the main circulating part of the primary circuit.

One such location that has experienced problems in PWRs is the canopy seals associated with control rod drive mechanisms. Canopy seals ensure leak tightness of threaded joints that make up the control rod housings above the PWR pressure vessel top head. The threaded joints impede evacuating air during filling of the primary circuit and obviously do not allow free circulation of the primary coolant to the canopy seal. One publication has discussed the origin of canopy seal cracking and leaks in some detail in relation to a few plants (Ref 55). Searches of nuclear industry records of service failures show, however, that this is a widespread generic problem affecting many PWRs worldwide. It divides broadly into two families of failures—those occurring rather rapidly a year or two after entering service and those occurring after more than about 10 years' service (Ref 1). The first group usually has some aggravating mechanical factor associated with poor welding of the canopy seal closure. In the second case, even if welding defects are present, it is far from clear that these are always directly associated with the cracking.

The interpretation of canopy seal cracking has been based on its mainly transgranular morphology, seemingly typical of transgranular stress corrosion cracking (TGSCC) of (non-sensitized) austenitic stainless steels in the presence of chloride and oxygen (Ref 55). Figure 13 shows the classical relationship between oxygen and chloride concentrations that gives rise to TGSCC of nonsensitized stainless steels. It can be seen that any oxygen trapped in this location

greatly reduces the tolerance of austenitic stainless steels for chloride contamination. Chloride impurity concentrations acceptable for normal quality primary water would be unacceptable where a trapped air bubble at the high primary circuit pressure is present. Even if the consumption of oxygen by general corrosion is taken into account, such a trapped bubble could be present for a long time, more than sufficient to cause cracking.

The only difficulty with the foregoing interpretation is that the few analyses available of the liquids trapped behind canopy seals hardly ever show any significant chloride, the main impurity being sulfate. The presence of sulfate as the major impurity is not surprising either as a surface impurity on nearby threaded surfaces or from the thermal decomposition of any resin fines that find their way accidentally into the hot parts of the primary circuit. Given that sulfate in combination with oxygen is well known to cause stress corrosion in BWRs, albeit usually intergranular, it is possible that a similar mechanism could be at work in dead legs of PWRs. In addition, recent studies have shown that the combination of very low amounts of chloride and sulfates (of the order of a few ppm) in the presence of dissolved oxygen can promote very fast transgranular cracking of type 304 stainless steel at moderate temperatures of $\sim 200^\circ\text{C}$ (390°F) or less (Ref 57).

High-Strength Stainless Steels

Several high-strength stainless steels are used in PWR primary circuits for components such as bolts, springs, and valve stems. The main ones considered here are A-286 precipitation-hardened austenitic stainless steel, type 410 and similar martensitic stainless steels, and 17-4PH precipitation-hardened martensitic stainless steel. Over the years, small numbers of such components have cracked due to stress corrosion or hydrogen embrittlement and, on occasions, loose parts have been generated in the primary circuit.

Alloy A-286 is, an austenitic, precipitation-hardened, stainless steel (Table 2) that is strengthened by γ' , $\text{Ni}_3(\text{Ti},\text{Al})$, formed during aging at 720°C (1330°F). Its use is favored where the expansion coefficient relative to other austenitic stainless steels is an important design factor. Unfortunately, it is susceptible to IGSCC in PWR primary water when loaded at or above the room-temperature yield stress, typically 700 MPa (102 ksi) (Ref 58–63). Cold work prior to aging in combination with the lower of two commonly used solution annealing temperatures of 900°C and 980°C (1650°F and 1795°F) has a particularly adverse effect on resistance to IGSCC (Ref 61). Hot heading of bolts, which can create a heat-affected zone between the head and shank, is another known adverse factor. Nevertheless, even if these metallurgical factors are optimized, immunity from cracking cannot be ensured unless the stresses are maintained

below the room-temperature yield stress, which necessitates strictly controlled bolt loading procedures. There is also strong circumstantial evidence that superimposed fatigue stresses can lower the mean threshold stress for IGSCC even further. Finally, the role of impurities, including oxygen introduced during plant shutdown and possibly consumed only slowly in confined crevices, in helping crack initiation is clear from all the evidence available. Once initiated, cracks grow relatively easily even in well-controlled PWR primary water (Ref 62).

Martensitic Steels. Components such as valve stems, bolts, and tie rods requiring rather high strength combined with good corrosion resistance in PWR primary circuit water have been typically fabricated from martensitic stainless steels, particularly type 410 and 17-4 PH (Table 2). A search of the nuclear industry literature reveals a significant number of failures of martensitic stainless steels such as type 410, for example in Nuclear Regulatory Commission (NRC) Information Notices (Ref 64). In most cases, the affected components have usually entered service in an overly hard condition due to tempering at too low a temperature. No in-service aging seems to have been involved, these materials proving susceptible to SCC/hydrogen embrittlement in the as-fabricated condition. An additional problem has been caused by galvanic corrosion with graphite-containing materials in the packing glands of valves, sometimes leading to valve stem seizure. The preferred replacement material has often been 17-4 PH with its higher chromium and molybdenum content no doubt conferring better resistance to crevice corrosion.

A significant number of service failures of 17-4 PH precipitation-hardening stainless steel have also occurred in PWR primary water (Ref 65–67). Initially, intergranular cracking by SCC/hydrogen embrittlement was associated with the lowest temperature aging heat treatment at 480°C (900°F) designated H900. This gives a minimum Vickers hardness value of 435 HV, clearly in excess of the limit of 350 HV commonly observed to limit the risk of hydrogen embrittlement. The 593°C (1100°F) (H1100) aging heat treatment was subsequently widely adopted and normally yields a hardness value below 350 HV. Nevertheless, a small number of failures, due either to brittle fracture or SCC/hydrogen embrittlement, have continued to occur. The origin of these failures appears to be thermal aging in service.

Two main thermal aging mechanisms of martensitic stainless steels are recognized. The first, “reversible temper embrittlement,” is related to the diffusion of phosphorus to grain boundaries at aging temperatures generally above 400°C (750°F) and can occur in both type 410 and 17-4 PH stainless steels. The grain boundaries are consequently embrittled and are particularly susceptible to intergranular cracking by hydrogen embrittlement, but no general increase in hardness is observed. The

Fig. 13 Stress-corrosion cracking of austenitic stainless steels as a function of chloride and oxygen concentrations in high-temperature water. IGSCC, intergranular stress-corrosion cracking; TGSCC, transgranular stress-corrosion cracking. Source: Ref 56

embrittlement can be reversed by heat treating around 600 °C (1110 °F) and largely avoided by reducing the phosphorous content and by small alloying additions of molybdenum.

The second thermal aging embrittlement mechanism is relevant only to precipitation-hardened stainless steels such as 17-4 PH. It arises from an intragranular decomposition of the martensitic matrix into two phases, α , which is rich in iron, and α' , which is rich in chromium. A generalized increase in hardness is observed with corresponding increases in strength and ductile-brittle transition temperature and loss of fracture toughness. The hardening cannot be reversed without re-solution heating. French studies have shown that this aging mechanism can occur in 17-4 PH steels on time scales relevant to the design lives of PWRs at temperatures exceeding 250 °C (480 °F) and quantitative models for component assessment have been developed (Ref 66, 67). Mechanical fractures occur by cleavage, although those involving corrosion can also be intergranular. Both types of failure have been associated with hardness values after in-service aging significantly exceeding 350 HV. Corrosion-related failures have also been aggravated by impurities from valve packing gland materials.

Irradiation-Assisted Corrosion Cracking of Austenitic Stainless Steels

Irradiation-assisted stress corrosion cracking (IASCC) is a term that defines SCC phenomena in core structural materials of water-cooled and/or moderated nuclear power reactors in which neutron and/or γ irradiation contributes directly to the initiation and propagation of SCC. It is reviewed in detail in the article "Effect of Irradiation on Corrosion and Stress Corrosion Cracking in Light Water Reactors" in this Volume and so is only briefly described here. By implication, in the absence of material damage by fast neutrons and/or modification of the environmental chemistry by ionizing radiations, SCC either does not occur or is significantly less severe. Laboratory and field data show that intergranular SCC of austenitic steels can result from long-term exposure to high-energy neutron radiation (Ref 68–72).

Types 304 and 316 austenitic stainless steels, usually solution annealed and cold worked respectively, are widely used for the fabrication of light water reactor core internals. Unlike fuel elements that are discharged and replaced after a few reactor cycles, the internals are intended to remain for the complete reactor life. Consequently, extremely high neutron doses can be experienced by components in close proximity to the nuclear fuel. Both BWR and PWR core internal structures have experienced cracking attributed to IASCC. An overview of these incidents together with the anticipated end-of-reactor-life doses and characteristic dose ranges

for the irradiation-induced physical processes likely to be important in IASCC are shown in Fig. 14 (Ref 70–72).

In the case of the oxygenated coolants of BWRs, the modification of grain-boundary composition due to neutron irradiation and resulting inverse Kirkendall diffusion of point defects, particularly chromium depletion, has been shown to be an important precursor of IASCC. Neutron doses exceeding 5×10^{20} n/cm² ($E > 1$ MeV) are associated with the occurrence of IASCC in BWRs, this being the dose required to develop sufficient irradiation-induced chromium depletion at grain boundaries. In addition, the formation of oxidizing species, oxygen and hydrogen peroxide, by radiolysis plays an important role in this manifestation of IASCC.

Pressurized water reactor field experience has also shown that intergranular cracking of highly irradiated core components can occur. Specifically, type 304 cladding of both control rods and (now obsolete) fuel pins as well as cold-worked type 316 core baffle-former bolts of some first generation (CP0 series) 900 MW French PWRs have cracked intergranularly in service (Ref 70, 72). Fast neutron doses of $> 2 \times 10^{21}$ n/cm² ($E > 1$ MeV) and strains $> 0.1\%$ have been implicated in the cracking. The same irradiation-induced modification of grain-boundary chemistry accompanied by very significant hardening is observed in stainless steels irradiated in PWRs. Indeed, this occurs to a much greater extent than in BWRs due to the higher neutron doses for equivalent operating times. However, as noted earlier, radiolytic formation of oxygen or hydrogen peroxide is effectively suppressed in PWRs by the addition of 2 to 4 ppm of hydrogen to the primary water coolant. The absence of such oxidizing species is an obvious environmental difference compared with BWRs and renders grain-boundary chromium depletion of no particular consequence in PWR primary water. The specific radiation-induced microstructural and microchemical changes induced by neutron irradiation in PWRs responsible for IASCC susceptibility have not so far been identified, although the considerable irradiation-induced hardening that is observed no doubt plays an important role (Ref 71).

A factor specific to the PWR core baffle-former bolts is the presence of a closed crevice in the particular CP0 series of French 900 MW plants concerned (Ref 70, 72). This has led some investigators to speculate that local radiolytic production of oxidizing species might occur due to limited access of hydrogen. However, no evidence of oxidizing conditions has been found on extracted bolts. Laboratory simulations of crevices irradiated at intensities equivalent to in-core conditions have also failed to reveal the formation of any oxidizing species within the crevice (Ref 68). An alternative hypothesis for baffle bolt cracking is that local boiling due to γ heating could render the confined environment strongly caustic by concentrating lithium

hydroxide in the liquid phase. Again, there is no evidence for this in the form of mineral precipitates containing boron that are observed when PWR primary water is allowed to boil (as, for example, in the case of the axial offset anomaly discussed previously in this article).

In addition to the phenomena of radiation-induced hardening and changes to grain-boundary composition, other radiation damage processes could have important influences on the development of IASCC (Ref 70, 72). Irradiation creep can relax residual and applied stresses and is independent of temperature in the range of interest to light water reactors. Swelling, hitherto only considered of importance to fast reactors, could in principle also appear at the high neutron doses associated with the second half of life of PWRs and affect the loads applied to components such as baffle bolts. Thus, although significant advances have been made in the understanding of IASCC, much remains to be learned, and it is today a very active field of research in the context of both BWR and PWR plant aging.

Steam Generator Secondary Side Corrosion

The two types of PWR steam generators in general use are vertical recirculating steam generators (RSGs) and once-through steam generators (OTSGs) (Fig. 5) with tube bundles, depending on age, made from either mill-annealed or thermally treated Alloy 600, or thermally treated Alloy 690, or Alloy 800. Sub-cooled primary water flows through the inside of the tubes and boils secondary water on the shell side of the tubes. The steam quality of the water-steam mixture entering the steam driers of RSGs is typically 10% and the superheat across the tubes may vary from 10 to 40 °C

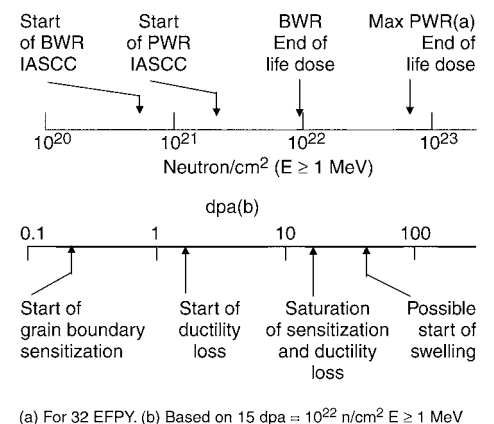

Fig. 14 Summary of irradiation-assisted stress-corrosion cracking (IASCC) in light water reactors and associated metallurgical changes in austenitic stainless steels as a function of neutron irradiation in n/cm² ($E \geq 1$ MeV) or displacements per atom (dpa). (20 to 70 °F). In OTSGs, which of necessity have always used all-volatile water treatment (AVT) water chemistry, the steam quality reaches 100% at the ninth and tenth support plate region, and achieves about 20 to 35 °C (40 to 60 °F) of superheat at the top of the unit. Recirculating steam generators of Russian designed Voda-Vodyanoi Energetichesky Reaktor (VVER) plants are rather different being horizontal with stainless steel tubes running between two large vertical cylindrical collectors for the inlet and outlet primary water.

Vertical PWR steam generators have experienced a variety of corrosion-induced and mechanically induced problems, and many steam generators have been replaced, usually because of SCC of mill-annealed Alloy 600 steam generator tubes (Ref 15, 28, 73). Some have been replaced after only 8 to 12 years of operation, which is far short of the usual initially licensed plant operating period of 40 years. Secondary side corrosion problems include flow-assisted corrosion of carbon steel pipes and denting, wastage, intergranular attack, IGSCC, and pitting on the outside surfaces of the steam generator tubes (Ref 15, 28, 73). The evolution of steam generator tube corrosion with time in terms of relative importance of each damage mechanism is shown in Fig. 6. Mechanical concerns have included water hammer, thermal stratification in secondary feedwater pipes, and fretting and wear of the tubes caused by excessive tube vibration.

As remarked earlier, the vast majority of PWR steam generator corrosion problems, particularly on the secondary side, have concerned mill-annealed Alloy 600. In Germany, Kraftwerk Union AG (KWU) and later Babcock & Wilcox/Atomic Energy of Canada Limited (B&W/AECL) designs for the Canada deuterium uranium (CANDU) series of pressurized heavy water reactors (PHWRs), the tubes were made of Alloy 600. The mill-annealing conditions for Alloy 600 varied among the manufacturers, while B&W/AECL stress-relieved the completed steam generators (605 °C, or 1125 °F, for 8 h) including the Alloy 600 tubing. This latter procedure inevitably "sensitized" the tubing (by precipitating chromium carbides on the grain boundaries and leaving a chromium-depleted band, typically a few tens of micrometers wide, adjacent to grain boundaries). Subsequently, Alloy 600 tubing was thermally treated (705 °C, or 1300 °F, for 15 h) to improve resistance to IGSCC, and to date this tubing has largely resisted secondary corrosion problems. New or replacement RSGs are supplied with thermally treated Alloy 690 or Alloy 800 tubing, which, to date, have also resisted both primary and secondary corrosion problems.

Many secondary side corrosion problems with mill-annealed Alloy 600 tubes have been associated with the interstices between the tubes and the tube supports. The tube support structures for most of the early units were made of carbon steel, while later units switched to types 405, 409, and 410 ferritic stainless steels

for additional corrosion resistance (Ref 74). Type 347 austenitic stainless steel has always been used for KWU steam generator tube egg crate (lattice bar) support structures. Tube support structures of early units used plates with drilled holes, then plates with trefoil or quatrefoil broached holes initially with concave lands and then flat lands, or lattice bars (egg crates) (Fig. 15). The objective of the more open tube support designs is to reduce the accumulation of impurities in the interstices by the phenomenon of hideout.

Another corrosion-sensitive zone for steam generator tubes has been in and just above the lower tube sheet. In some of the very early RSG designs, the tubes were only partly expanded just above the seal weld with the lower tube sheet face, thus leaving a crevice between the outside diameter (OD) of the tube and the inside diameter of the hole in the tube sheet. Later, the tubes were expanded into the tube sheet along nearly their full length in order to close all but the last ~4 mm (0.16 in.) of the tube to tube sheet crevice. Tube expansion has been achieved by various methods, mechanical rolling, hydraulic, and explosive. Each expansion method has generated its own characteristic residual stress fields in the tubes that have influenced subsequent stress corrosion behavior if, or when, impurities concentrate by hideout either in the tubesheet crevice or under sludge that accumulates on the upper face of the tube sheet.

The underlying cause of nearly all forms of localized corrosion observed on the secondary side of steam generators is the phenomenon of hideout of low volatility solutes present as impurities, or added deliberately, in superheated crevices with restricted water circulation. Such impurities entering recirculating steam generators in the feed water are relatively insoluble in the steam phase so that they accumulate in the recirculating water. However, their concentration is limited in the recirculating water to about 100 times that of the concentration in the feed water by maintaining a blowdown of recirculating water equivalent to about 1% of the steam mass flow. Significant further concentration of impurities by potentially many orders of magnitude then occurs in occluded superheated crevices by a wick boiling mechanism. Due to the potential variety of impurities entering the steam generators, many complex mixtures of chemicals can be envisaged in these occluded regions where such impurities concentrate by hideout. This severely complicates the task of understanding the mechanisms of tube corrosion and defining adequate remedies. Tube damage such as wastage, pitting, and denting has been attributed to the local formation of strong acids and, evidently, has been largely eliminated by appropriate management of secondary water chemistry (Fig. 6). By contrast, the steadily rising trend in IGA/IGSCC (Fig. 6) suggests that countermeasures have not been completely effective, probably because its

origin(s) has/have not always been correctly identified. All these different degradation mechanisms are described in more detail hereafter along with the remedies adopted.

Tube Wastage

Tube wastage, or thinning, was one of the first corrosion problems that occurred in RSGs operating with sodium phosphate as a secondary water treatment (Ref 15, 75). It was first observed in commercial PWR plants when phosphate treatment was changed to a low sodium-to-phosphate molar ratio control, in which the molar ratio of Na/PO_4 was maintained at about 2.0. This change was in response to a series of caustic stress corrosion events attributed to operation with uncontrolled high Na/PO_4 ratios (above 2.8), from which free caustic could result. Although the incidence of caustic IGSCC dropped markedly, wastage began to be observed within approximately 1 year after the water chemistry change.

Phosphate wastage in PWR steam generators occurred typically at the interfaces between hot-leg tubes and the tops of sludge piles that accumulated on top of the tube sheet. Where the sludge pile was deep, the zone of wastage extended about 25 mm (1 in.) into the pile, but in most cases, it did not penetrate appreciably into the tube/tube sheet crevice. Wastage was first noted in steam generators of a particular design in the vicinity of antivibration straps, which were relatively wide and oriented in such a way as to define a region of steam blanketing. Corrosion was concentrated at the boundaries of this steam-blanketed region, where a liquid/vapor interface presumably fluctuated over a short length of tubing.

Laboratory work showed that the aggressiveness of concentrated sodium phosphate solutions was related to both concentration and the Na/PO_4 molar ratio and led to recommendations for the Na/PO_4 molar ratio to be controlled in a relatively narrow band from 2.3 to 2.6. The lower limit was related to the rapidly increasing rate of wastage at lower ratios, and the higher limit was selected to avoid free caustic forming. Some plant operators were successful in controlling their steam generator chemistries within this restricted range of compositions, but eddy-current inspections indicated that the rate of attack only slowed but did not stop. Furthermore, a constantly increasing sludge burden, augmented by precipitated phosphate compounds, made such ion ratio control increasingly difficult. One explanation based on laboratory work linked continuing wastage to the formation of an extremely corrosive immiscible liquid phase for Na/PO_4 ratios between 2 and 2.8 at temperatures greater than about 273 °C (523 °F) (Ref 75). In view of the continuing wastage observed in service, the vendors of the affected plants recommended that the plant operators adopt an all-volatile water treatment based on the use of ammonia and hydrazine, and this was

almost universally followed with the exception of a few lower temperature plants. However, as described subsequently, this change led to other corrosion problems, namely denting.

Denting

Denting was discovered in 1975 when eddy-current probes were prevented from passing through tube/tube support plate intersections due to tube deformation and associated diameter restrictions (Ref 15, 28, 76). By 1977, denting had become a widespread problem. Denting occurs when the surfaces of the hole in a carbon steel tube support plate corrode to the point at which the iron corrosion products, of volume several times greater than that of the iron from which they came, squeeze and deform the steam generator tubing (and the tube support plate). The cause of denting is best explained by Potter-Mann-type linear accelerated corrosion, in which a nonprotective oxide layer is formed as the corrosion progresses. Sample intersections of tubes and support plates removed from dented steam generators have shown local chloride concentrations of over 4000 ppm accumulated by hideout in the dented region. The source of chloride was generally condenser leakage, particularly at plants cooled by seawater.

Tube deformation has also been reported in some steam generators with carbon steel egg crate supports, implying that concentration of aggressive impurities and carbon steel corrosion may also occur with this design. Similarly, distorted eddy-current signals (dings) have been observed at the ninth and tenth support plates of OTSGs that use a support plate with a trefoil hole design (Ref 15, 25). This is the most likely region for support plate corrosion because it is where dryout and most of the deposition of any low volatility chemicals present in the feedwater occur. However, it is also possible that dings may be caused by tube vibration and impact on the tube support plates. Denting was also observed at the top of the tubesheet crevice in several RSGs but progressed at a slower rate. However, denting has not been reported in steam generators where the support structures are fabricated from type 347 stainless steel or in units that have used lattice bars and broached hole plates made from type 410 stainless steel.

Several major consequences can result from the uncontrolled progression of denting: tube cracking and leaking at U-bends, tube cracking at the constricted crevices, tube support ligament failure, and gross deformation of tube support plates. Laboratory tests have shown that denting was caused by the presence of a high concentration of acidic chlorides in the support plate crevice and the presence of an oxidizing environment outside the crevice (Ref 77). Concentration factors of greater than 20,000 times within crevices have been observed in laboratory tests.

Mitigating Denting Problems. Based on this knowledge of the causes of denting, corrective actions for operating plants were

developed to modify the environments and make them less aggressive. These included reducing condenser impurity in-leakage, reducing air in-leakage, producing purer makeup water, and using condensate polishers to purify the feedwater. Another approach employed to modify the environment has been the addition of boric acid, which inhibits acidic chloride attack (Ref 78). The application of these corrective methods greatly reduced denting rates as seen in Fig. 6.

For new plants, the formation of aggressive environments can be minimized by switching from drilled to broached support plates with flat lands with which the concentration of chemicals within the tube/tube support crevice is greatly reduced. For new plants, more corrosion-resistant materials have been used for tube supports such as types 405, 409, and 410 stainless steels (Ref 74, 76).

Pitting

Extensive pitting on the outer surfaces of mill-annealed Alloy 600 tubes has been observed in a few cases. This pitting occurred primarily on the cold leg between the tube sheet and the first support plate in regions where sludge or tube scale was present (Ref 15). Metallographic sections showed a laminar appearance caused by the presence of metallic copper layers. In addition, the corrosion deposit was enriched in chromium and depleted in nickel and iron compared with the base metal. Laboratory tests have shown that pits can be formed above about 150 °C (300 °F) in the presence of high chloride ion concentrations from either seawater or copper chloride (Ref 79). Thus, it was concluded that the pits were caused by chloride, low pH, and an oxidant such as cupric chloride (CuCl_2) or oxygen coming from brass condenser tube leaks. Sludge and scale could also have enabled the bulk impurities to be concentrated by the hideout mechanism in addition to the classical electrochemical oxygen concentration cell mechanism.

Mitigating Pitting Problems. The principal corrective action is to modify the environment to make it less corrosive as in the case of wastage. One approach has included reducing the sludge and scale by minimizing the entry of solids (with higher pH and reduced air in-leakage), by sludge lancing, and by chemical cleaning. Another approach has included minimizing the entry of soluble contaminants (principally chlorides and oxidants), by quickly repairing leaky condensers, and by deaerating auxiliary feedwater used for hot standby.

Intergranular Attack and IGSCC at the Outside Surface

This section provides a summary of field observations of intergranular corrosion in its various forms, most notably intergranular attack

(IGA) and intergranular stress corrosion cracking (IGSCC). It also reviews laboratory studies that have resulted in models and computer codes for evaluating and predicting intergranular corrosion, and discusses remedial actions for preventing or arresting intergranular corrosion. Additional information on intergranular corrosion can be found in *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, of the *ASM Handbook*.

Summary of Field Observations

Intergranular corrosion of mill-annealed Alloy 600 tubes has been experienced in many steam generators operating at seawater- or freshwater-cooled locations (Ref 15, 28). As shown in Fig. 6, this mode of attack has grown in importance, unlike the other modes of attack discussed previously, and is increasingly responsible for premature steam generator replacement. The rate of propagation has been shown to vary widely and, in some cases, has been sufficiently rapid to require mid-cycle inspections and unscheduled outages to plug or repair leaking tubes. The associated economic loss to PWR operators has been significant. Fortunately, most of the corrosion has been confined to crevice locations so that leaks have been small and without risk of a large rupture.

Pressurized water reactor steam generators with mill-annealed Alloy 600 tubes are gradually being replaced due to stress corrosion damage on both primary and secondary sides of the tubes. The newer designs incorporate improvements to limit the fouling of crevices that precedes impurity hideout. The tubes are also fabricated from Alloy 690 or 800 that are more resistant to most of the environments that are hypothesized to exist in superheated crevices and under sludge piles on the secondary side. The population of PWR steam generator tube bundles at immediate risk from IGA/IGSCC is therefore reducing although many mill-annealed Alloy 600 tube bundles still remain in service. In addition, although thermally treated (715 °C, or 1320 °F, for 16 h) Alloy 600 tube bundles are proving very much more resistant to IGA/IGSCC, doubts remain as to their viability over the standard (initial) 40 year licensing period.

Intergranular SCC in mill-annealed Alloy 600 steam generator tubing is illustrated in Fig. 16. The SCC morphology consists of single or multiple major cracks with minor-to-moderate amounts of branching that are essentially 100% intergranular. Experience suggests that IGSCC requires stresses greater than 0.5 yield in order to propagate rapidly. At lower stresses, propagation rates may approach zero, or the corrosion may take the form of intergranular corrosion, which is frequently called “intergranular attack” (IGA).

Intergranular attack is the second generally recognized form of secondary side corrosion attack of mill-annealed Alloy 600 where there is substantial volumetric attack of every grain-boundary, as illustrated in Fig. 17. Stress is not strictly necessary for IGA to occur, which

distinguishes it from IGSCC. Nevertheless, the two are closely related, as is apparent in Fig. 17, where stress-assisted fingers of IGA penetrate deeper than the layer of uniform IGA. The microscopic morphology of secondary side cracking observed in service is often that of IGA near the OD surface developing into finger-shaped IGA penetrations and finally into IGSCC toward the primary side. There is a strong presumption that as IGA gradually deepens, its morphology changes to that of IGSCC, although there is no proof that the two forms of attack occur in that order. Figure 18 shows a particularly severe case of IGA/IGSCC from a steam generator that has since been retired and replaced (Ref 80). The detailed morphology of the IGA may vary somewhat from case to case with islands of more resistant grain boundaries sometimes giving a cellular appearance to the IGA.

Combined IGA/IGSCC was first observed in the tube/tube sheet crevice (an annular gap remaining after manufacture of the earliest PWR steam generators) before full depth rolling was generally adopted. However, corrosive attack of mill-annealed Alloy 600 steam generator tubes occurs most commonly in the crevices between the tubes and tube support plates fabricated from carbon steel with cylindrical holes (Ref 28). Stress-corrosion cracking is also observed under the sludge piles that accumulate on tube sheets and can even be located up to several centimeters below the top surface of the tube sheet, despite tube expansion into the tube sheet. There has been a relatively recent trend for circumferential SCC also to occur near the tube sheet surface, although most IGSCC is observed in the axial direction of the tubes. A small

number of thermally treated Alloy 600 tubes whose thermal treatment was found to have been unsatisfactory have also suffered from IGA/IGSCC. However, to date (early 2004), neither thermally treated Alloy 690 nor Alloy 800 have been affected. Some IGA/IGSCC has also been reported for plants with quatrefoil broached carbon steel support plates and mill-annealed Alloy 600 tubing but not with quatrefoil broached ferritic stainless steel support plates (Ref 81).

In mill-annealed Alloy 600 tubing, IGA/IGSCC is much more prevalent at the lower levels in recirculating steam generators where

Fig. 17 Intergranular attack of an Alloy 600 steam generator tube (etched sample). Source: Ref 15

the temperature difference between the primary and secondary fluids is greatest (Ref 82). This is clearly strong evidence for the importance of impurity hideout, which increases as a function of the available superheat on the secondary side. Broached tube support plates minimize the extent of the narrow gap between the tube and its support plate and hence substantially reduce the tendency for impurity hideout in such locations.

When the fraction of tubes affected by IGA/IGSCC at tube support plate intersections is plotted as a function of time on Weibull coordinates, it is observed that the slopes of the Weibull plots can be rather high, typically between 4 and 9 (Ref 41, 81). This indicates that once IGA/IGSCC starts, its progression to other tubes is quite rapid and relatively consistent among different plants. On the other hand, incubation periods before cracking starts vary considerably. In some cases, IGA/IGSCC has not been observed at all, even on mill-annealed Alloy 600 tube bundles after very long periods of operation. There is a tendency to attribute this variability among different plants mainly to differences in secondary water chemistry and impurities. However, heat-to-heat variability in sensitivity of mill-annealed Alloy 600 to IGA/IGSCC is very important in this respect and the proportion of very sensitive heats varies markedly in different steam generators (Ref 1, 81).

Following the retirement of some steam generators with degraded mill-annealed Alloy 600 tubing, it has been possible to extract and observe metallographically complete tube/tube support plate intersections (Ref 83). These studies have revealed that cylindrical crevices between the tubes and tube support plates are plugged at their entrances and exits with a low porosity (<10%) solid mixture of magnetite and silica. In the center of the crevices, the deposits are mainly magnetite with porosity much higher at around 50%. These features are illustrated in Fig. 19 (Ref 84). Curiously, the tubes appear to be centralized in the crevices by the buildup of deposits and corrosion products. This fouling and plugging of the crevices between tubes and carbon steel tube support plates with cylindrical tube holes is generally acknowledged to be widespread. One consequence is that high forces have become necessary to extract tubes for destructive examination, indicating that the tubes no longer slide easily in the tube support plates as intended by the design.

Deposits found on extracted steam generator tubes have also been examined in detail (Ref 84). On the tube free spans, magnetite deposits are observed overlying a protective nickel/chromium spinel oxide. Within the tube support plate crevices, thin layers rich in alumino-silicates have been observed on the heat transfer surfaces associated with poorly protective oxide films and the presence of IGA/IGSCC.

In some special cases, IGA/IGSCC has also been observed on the free spans of tubes of

recirculating steam generators (Ref 28). There are two circumstances where this has occurred. The first is where deposits rich in silica have formed bridges between tubes associated with particularly high and localized heat fluxes. In this case, a crevice is created by the deposits rather than by a design feature so that the fundamental degradation processes occurring under the deposits are probably the same as at tube support plate intersections. The second special case is where lead blankets used for radiological protection have been accidentally left in steam generators after maintenance operations. In these cases, widespread tube free span IGA/IGSCC has been observed. It is well known that lead causes severe IGA/IGSCC of Alloy 600 and other potential tube alloys. What is more difficult to ascertain is whether the traces of lead that are found in nearly every steam generator have a similar bad influence in crevice geometries (Ref 85).

One final feature of steam generator tube degradation that should be mentioned is the relatively recent appearance after about 20 years' service of IGA/IGSCC in the superheated steam zone of OTSG (Ref 25). This tube degradation is associated with scratches on the tube outer surfaces created during tube installation but, unlike most recirculating steam generators, is found on the tube free span between the tube support plates and not in crevices. Nevertheless, the IGA/IGSCC shows strong similarities on the microscopic scale with tube degradation in recirculating steam generators. As noted earlier, a significant difference between OTSG and recirculating steam generators is that the former were stress relieved before entering service and this gave rise to grain-boundary sensitization (i.e., chromium depletion) of the Alloy 600 tubes. The associated presence of chromium carbides on the grain boundaries has been generally regarded as a favorable property improving resistance to IGA/IGSCC (and PWSCC) of these sensitized tubes, whereas the chromium depletion seems to be of no particular significance in deoxygenated secondary (or primary) circuit water.

Laboratory Studies

There is little doubt that the phenomenon of hideout of impurities in crevice geometries of recirculating steam generators lies at the heart of the localized corrosion problems of the tubes that have been encountered. It has been known since the nineteenth century that steam leaks through the riveted joints of steam locomotives and similar boilers caused impurities to concentrate by local evaporation. This usually created a concentrated alkaline liquid at the liquid-vapor interface, which then caused caustic cracking of the boiler shell, sometimes with catastrophic consequences.

The same basic phenomenon has been demonstrated many times in model boiler studies simulating PWR recirculating steam generators

(Ref 82). The concentrations of soluble impurities so generated can be amazingly high. By definition, the crevice liquid must have a boiling point equal to the primary side temperature and a vapor pressure equivalent to that of the secondary side pressure. The temperature difference between the primary and secondary sides of PWR steam generator tubes may vary from 45 °C (80 °F) at the base of the hot leg to 22 °C (40 °F) near the upper U-bends. At these degrees of superheat, impurity concentrations of between 25 and 15 M are necessary in order for such solutions to remain in the liquid state at the secondary side pressure. Recent work has shown that only NaOH (and by analogy, KOH) can support superheats >25 °C (45 °F) and remain liquid at the temperature and pressure of PWR steam generators (Ref 86). Sodium chloride can give rise to concentrated solutions with up to 25 °C (45 °F) superheat before precipitation intervenes, while most other impurities such as sulfates and silicates are so insoluble that they can only generate solutions with a few degrees of superheat at most. Thus, of the common impurities that enter steam generators, only NaOH is likely to form a concentrated liquid that can wet the tube OD surfaces (Ref 82), and in other cases, steam blanketing is more likely. However, the presence of silica deposits in the tube/tube support plate crevices, particularly on the heat transfer surface, is incompatible with the formation of highly alkaline crevice environment. Silica is an effective buffering agent in these circumstances that would ensure an upper limit of pH of about 10 at temperature. This may nevertheless be sufficient to cause caustic cracking of Alloy 600 because the minimum pH for this mode of SCC is about 9 at temperature.

Computer codes have been developed to describe the solutions formed by hideout of which the best known for application to PWR

Fig. 19 Sketch of fouled steam generator (SG) tube/tube support plate (TSP) crevices after many years of operation. Source: Ref 84

steam generators is MULTEQ (Ref 87). It has a large thermodynamic database and the calculation routine minimizes the Gibbs free energies of a given chemical system at equilibrium. Various boundary conditions can be imposed such as for static or flowing systems, for evaporation of water at constant temperature or pressure, and removal or retention of vapor and precipitates as they are formed. The code is typically used to calculate the composition of an assumed concentrated fluid present in a superheated crevice. In practice, a concentration factor, which can be as large as 10^6 , is applied to the chemical composition of diluted impurities analyzed during hideout return. Hideout return occurs when the steam generator is shut down and the thermal driving force for hideout is removed. The easily soluble impurities then diffuse back into the bulk steam generator water where they can be measured, albeit as very dilute solutions.

Clearly, a code such as MULTEQ can be only as reliable as the thermodynamic database on which it relies and the assumption that the measured hideout return impurities come from a concentrated solution in superheated crevices. The thermodynamic database has been steadily refined over two decades but is still lacking in critical data for the surprising variety of complex minerals found during careful examinations of the deposits formed under heat transfer conditions. Attempts to relate the occurrence of IGA/IGSCC in PWR steam generators with the compositions of the concentrated crevice fluids predicted by MULTEQ have failed to reveal any correlation (Ref 88). Such calculations in recent years have also often predicted neutral to mildly alkaline crevice liquids (assuming such a liquid phase is present) consistent with the deductions from analyses of crevice deposits.

Mathematical models have also been published that incorporate the kinetic aspects of transport of impurity species into tube/tube support plate crevices containing porous deposits (Ref 89, 90). These are very complex calculations including thermal hydraulic, diffusion, and mechanical parameters, and more recently, also electrochemical factors. Hideout due to the wick boiling mechanism is, however, predicted to dominate over any electrochemical contribution due to ion migration. The latter can occur under the influence of any potential difference that might exist between the inside and outside of the crevice if an oxidizing agent is present outside the crevice (such as oxygen or oxidized copper originating from condenser leaks). As an example of the application of such models, assuming a 10^{-7} M solution of NaCl (6 ppm) is present in the recirculating water, approximately one month is predicted to be necessary for the concentration of NaCl to establish its limiting concentration in the crevice solution for the assumed geometry and heat transfer conditions. The crevice is predicted to be half full of this solution of limiting concentration after about 1 year.

Environmental Contaminants. At least seven classes of environmental contaminants have been postulated at various times to explain the occurrence of IGA/IGSCC of mill-annealed Alloy 600 (Ref 73, 91):

- High concentrations of sodium hydroxide (NaOH) and/or potassium hydroxide (KOH)
- The products from the reaction of sulfate ions with hydrazine or hydrogen (reactive low valence sulfur-bearing species are postulated)
- The products of thermal decomposition of ion exchange resins (sulfates and organic residuals)
- Highly concentrated salt solutions at neutral or nearly neutral pH (these salt solutions are the natural consequences of condenser leakage concentrated to high levels by the boiling processes in the steam generator)
- Alkaline carbonates and/or their reaction or hydrolysis products and alumino-silicate deposits (believed to affect the nature of the passive film on the alloy surface)
- Lead contamination
- Polluted steam

All these different modes of SCC of Alloy 600 have been reviewed extensively (Ref 92). Evaluation and modeling of tube damage by IGA/IGSCC in mill-annealed Alloy 600 has, nevertheless, traditionally been based on the assumed formation of solutions in occluded superheated crevices with extreme values of pH less than 5 or greater than 10 at temperature (see Fig. 2) (Ref 82, 93). In practice, most cases have been attributed to caustic cracking and appropriately draconian measures have been taken to restrict as much as possible sodium impurities into steam generators (see Table 4). A few cases of SCC in operating steam generators have been clearly caused by lead, sometimes, but not necessarily, with a marked transgranular component to the cracking. Lead-induced cracking occurs across the whole feasible range of pH. Whether the minor amounts of lead found in practically every steam generator have a critical influence on IGA/IGSCC behavior of Alloy 600 as distinct from aggravating another underlying degradation mechanism remains unresolved (Ref 85). The latter option seems likely in the view of the widely varying and erratic distributions of lead traces found on steam generator tubes.

Remedial Actions

Modification of the crevice environment can appear at first sight to be the most straightforward method of preventing or arresting intergranular corrosion, although implementation can be complicated due to existing deposits impeding access of secondary water to the occluded zone. Attempts to modify the crevice environment have included several factors, such as lowering the temperature, adding a pH

neutralizer or buffering agent such as boric acid, removing the aggressive species by flushing or soaking, and changing the concentration and/or anion to cation ratio of bulk water contaminants (Ref 15). Laboratory studies with model boilers have shown the benefit of several of these corrective measures and some have been applied to operating steam generators.

The concentration of contaminants accessible to the crevice may be controlled by eliminating or reducing the entry of contaminants to the steam generator and by controlling the concentrating capability of the sludge pile above the crevice. Reducing the entry of contaminants is best accomplished by preventing condenser leaks, routing drains to the condenser (if condensate is subsequently treated), and properly treating makeup water sources. Use of full-flow condensate polishers for control of ionic species has not been shown to be effective in controlling the species that are probably responsible for IGA and IGSCC, in contrast to the successful control of chloride responsible for denting (Ref 15). Polishers are potential sources of sulfates (SO_4) and sodium (Na^+) if operated or regenerated improperly, and they do not effectively remove silica or organics. However, some plants have used these condensate polishers very effectively to minimize impurity entry into the steam generators.

Control of the sludge pile on the tube sheet, which is an effective concentrating medium, requires three courses of action:

- Effective, periodic sludge lancing
- Minimization of particulate transport by preventing air entry and/or providing for feed-water filtration, such as by powdered resin condensate polishers
- Preventing the entry of chemical species that tend to promote agglomeration

Chemical cleaning has been used to remove the sludge on the tube sheet and more recently, with varying degrees of success, from the interstices between the tubes and tube support plates.

Corrosion Fatigue

Some years ago, cracking of some Alloy 600 OTSG tubes from the outer surface occurred in the upper regions of several OTSGs before the more recent examples of IGA/IGSCC that occurred at scratches described earlier (Ref 15, 25, 73). It was concluded that these cracks were caused by corrosion fatigue resulting from small-amplitude vibration combined with the transport of impurities into the upper regions of the OTSG units, particularly in the open lane. Laboratory tests showed a decrease in Alloy 600 fatigue strength in the presence of chemicals that were judged to be present in these upper regions. A substantial decrease in fatigue resistance of Alloy 600 was observed in acid sulfate/silicate solution. The environment was selected to be consistent with that postulated to exist

in the region of interest at the top of an OTSG. The fatigue strength at 10^7 cycles at 289°C (552°F) was found to be approximately 56% of the value measured in air at about the same temperature. Aerated acid sulfate/silicate and alkaline sulfate/silicate environments had a less deleterious effect.

Potentially much more serious cracking attributed to a form of corrosion fatigue has been observed in a small number of low-alloy steel steam generator shells and in carbon steel feed water piping. The combination of fabrication and operational factors necessary for such cracking to occur in carbon and low-alloy steels has ensured that it has in reality been highly plant specific, as described subsequently.

Extensive circumferential cracking of the upper shell to cone girth welds of all the Indian Point 3 (Westchester County, NY) steam generators (model 44) was found in 1982 following a steam leak through one of more than a hundred circumferential cracks (Ref 94, 95). Similarly, the steam generator shells of six other plants (both model 44 and 51 steam generators) located in the United States and Europe were also observed to be cracked in the same location (Ref 95–98). In some cases, cracking recurred after local repairs by contour grinding.

The steam generator shell cracking was caused by an environmentally assisted cracking (EAC) mechanism and has been variously called *corrosion fatigue*, *stress-corrosion cracking*, or *strain-induced corrosion cracking*. In fact, the last seems most appropriate because it recognizes that although the cracking is environmentally controlled, a dynamic strain is necessary to maintain crack propagation (Ref 99). Consequently, crack extension tends to occur intermittently, alternating with pitting at the crack tip during quiescent periods.

This EAC mechanism observed for steam generator shell materials is well known and characterized both for bainitic low-alloy steels as well as for ferritic-pearlitic carbon-manganese steels used extensively in both conventional and nuclear power plants (Ref 99–101). In addition to the dynamic loading requirement usually caused by large thermal transients, cracking has been associated in practice with high residual welding stresses due to poor or nonexistent stress relief (Ref 94). The worst affected plants had weld repairs during fabrication of the final closure weld. In one case the girth weld was remade and stress relieved at a higher temperature of 607°C (1125°F) compared with 538°C (1000°F) originally. Water chemistry transients, particularly oxygen ingress, occurring at the same time as dynamic loading have also been strongly linked to the observed cracking. The effect of oxygen was exaggerated if copper corrosion products (e.g., from brass condenser tubes) were also present (Ref 95). The only metallurgical factors that appeared to play a role were the sulfur impurity concentration in the steel in the form of manganese sulfide, where the risk of cracking was greater the higher the sulfur content, and possibly also the free nitrogen

content via the phenomenon of strain aging (Ref 101). The practical resolution of steam generator shell cracking has been achieved mainly by contour grinding of existing cracks and by ensuring that auxiliary feed water is properly deoxygenated prior to use, particularly during plant startup.

In addition to these reported incidents of steam generator shell cracking, a very large technical literature exists concerning EAC of carbon and low-alloy steels in both nuclear and conventional power plant (Ref 99–101). The incidents range from those where fatigue plays a major part to those where the contribution to damage from mechanical fatigue loading is minor. For example, cracking of carbon steel feed water lines close to the steam generator nozzle observed in twenty-six U.S. and three German PWR plants has generally been attributed to thermal fatigue due to hot/cold water layering at low power, probably assisted by oxygen transients. Deaerator vessels, usually fabricated from carbon steel of a thickness requiring no stress relief following welding, have been the focus of particular attention following several explosions with fatalities (Ref 102). The observed cracking in these cases is usually transgranular cleavage-like in appearance, although it can occasionally be intergranular without

any obvious involvement of other chemical pollutants.

External Bolting Corrosion

High-strength martensitic and maraging steels are used in many external fastener applications in nuclear power reactors, and a significant number of failures of this class of component have occurred (Ref 22). Most have been described as corrosion-related failures. The problems encountered with external bolting have affected both support bolting and pressure boundary fasteners.

Failures of low-alloy (4340 and 4140) and maraging steel support bolting have been attributed mainly to hydrogen embrittlement. Steels with ultrahigh yield strengths greater than 1000 MPa (145 ksi) have failed due to a combination of excessive applied stresses and humid or wet environments collecting around the bases of components. Steels with lower yield strengths have also failed due to poor heat treatment or material variability. As a result of these failures, a review of SCC/hydrogen embrittlement properties of high-strength steels exposed to water or saltwater at low temperatures was carried out and regulatory guidelines

Fig. 20 K_{ISCC} limits for support bolting as a function of yield stress. Source: Ref 103

based on this information were published in the United States (Ref 103). Acceptability of high-strength bolting was based on a lower-bound approach to K_{ISCC} as a function of yield strength as shown in Fig. 20. This fracture mechanics-based approach has some attractions for defining a quality assurance procedure and for defect assessment. However, hydrogen cracks can start from free surfaces, usually in crevices; consequently, it is advisable also to have an upper-bound strength limit (normally defined by a hardness level acceptance criterion such as <350 HV) to guard against this eventuality.

The second category of bolt failures is concerned with the integrity of the primary pressure boundary at locations such as flanges of manway covers and valves. Most of these incidents have been caused by erosion-corrosion in PWR primary water leaks. A small number of failures among this category of bolt have been associated, however, with SCC/hydrogen embrittlement rather than wastage (Ref 22). The ferritic bolting steels involved were not out of specification but had been in contact with molybdenum disulfide lubricants. It has been postulated that the lubricant dissociated on contact with hot water to yield hydrogen sulfide, which is a severe hydrogen embrittling agent for ferritic steels. The remedies for this category of failures are nevertheless clear; avoid leaks at flanges by improved gasket design and avoid sulfide-containing lubricants.

Effect of Irradiation on Stress-Corrosion Cracking and Corrosion in Light Water Reactors

Gary S. Was and Jeremy Busby, University of Michigan
Peter L. Andresen, General Electric Global Research

A GROWING CONCERN FOR ELECTRIC POWER UTILITIES worldwide has been degradation in core components in nuclear power reactors, which make up approximately 17% of the world's electric power production. Service failures have occurred in boiling water reactor (BWR) core components and, to a somewhat lesser extent, in pressurized water reactor (PWR) core components consisting of iron- and nickel-base stainless alloys that have achieved a significant neutron fluence in environments that span oxygenated to hydrogenated water at 270 to 340 °C (520 to 645 °F). Because cracking susceptibility is a function of radiation, stress, and environment, the failure mechanism has been termed irradiation-assisted stress-corrosion cracking (IASCC). Initially, the affected components have been either relatively small (bolts, springs, etc.) or designed for replacement (fuel rods, control blades, or instrumentation tubes). In the last decade, there have been many more structural components (PWR baffle bolts and BWR core shrouds) that have been identified to be susceptible to IASCC. Recent reviews (Ref 1-5) describe the current knowledge related to IASCC service experience and laboratory investigations and highlight the limited amount of well-controlled experimentation that exists on well-characterized materials. This lack of critical experimentation and the large number of interdependent parameters make it imperative that underpinning science be used to guide mechanistic understanding and quantification of IASCC.

The importance of neutron fluence on IASCC has been well established. As shown in Fig. 1, intergranular SCC (IGSCC) is promoted in austenitic stainless steels when a critical "threshold" fluence is exceeded (such "thresholds" appear only in some tests, as discussed later). Cracking is observed in BWR oxygenated water at fluences above 2 to 5×10^{20} n/cm² ($E > 1$ MeV), which corresponds to about 0.3 to 0.7 displacements per atom (dpa). A comparable "threshold" fluence for IASCC susceptibility has been

reported for high-stress, in-service BWR component cracking and during ex situ, slow-strain-rate SCC testing of irradiated stainless steels. This indicates "persistent" radiation effects (material changes) are primarily responsible for IASCC susceptibility, although in situ effects such as radiation creep relaxation of weld residual stresses and increased stress from differential swelling can be important.

As with SCC behavior in unirradiated environments, the aqueous environment and stress/strain conditions also strongly influence observed cracking. While some investigators have observed limited intergranular cracking in inert environments, it is clear that the IASCC observations in the laboratory and in plants can only be accounted for by an environmentally assisted cracking mechanism (i.e., IASCC is not a purely mechanical, phenomenon). Water chemistry and electrochemical potential effects are reflected in

the sharp increase in IASCC cracking with increasing dissolved oxygen (Ref 1, 5). Cracking is typically not observed in hydrogenated water (i.e., BWR hydrogen water chemistry or PWR water) until a fluence level approximately four times greater than that observed for oxidizing water conditions is attained. Service experience has shown that higher stress components exhibit failures at lower fluence levels.

Recent work has enabled many aspects of IASCC phenomenology to be explained (and predicted) based on the experience with IGSCC of unirradiated stainless steel in reactor water environments. This continuum approach has successfully accounted for radiation effects on water chemistry and its influence on electrochemical corrosion potential. However, all radiation-induced microstructural, and microchemical changes that promote IASCC are not fully known. Well-controlled data from properly

Fig. 1 Neutron fluence effects on irradiation-assisted stress-corrosion cracking susceptibility of type 304 stainless steel in boiling water reactor (BWR) environments. PWR, pressurized water reactor; IASCC, irradiation-assisted stress-corrosion cracking; dpa, displacements per atom. Source: Ref 4

irradiated and properly characterized materials are sorely lacking due to the inherent experimental difficulties and financial limitations. Many of the important metallurgical, mechanical, and environmental aspects that are believed to play a role in the cracking process are illustrated in Fig. 2. Only persistent material changes are required for IASCC to occur, but in-core processes such as radiation creep and radiolysis also have an important effect on IASCC. The following section examines the current understanding of persistent material changes that are produced in stainless alloys during light water reactor (LWR) irradiation based on the fundamentals of radiation damage and existing experimental measurements.

Irradiation Effects on SCC

Gary S. Was, University of Michigan
 Peter L. Andresen, General Electric
 Global Research

Irradiation-assisted SCC can be categorized into radiation effects on the water chemistry (radiolysis) and on the material properties. The cracking response to changes in water chemistry is similar for both irradiated and unirradiated

materials, as is discussed later. In both cases, there is a steep increase in environmental cracking kinetics with a rise in the corrosion potential above about 100 mV standard hydrogen electrode (100 mV_{SHE}) (Ref 5–7). At high corrosion potential, the crack growth rate also increases sharply as impurities (especially chloride and sulfate) are added to pure water in either the irradiated or unirradiated cases. In postirradiation tests, the dominant radiation-related factors are microstructural and microchemical changes, which can be responsible for “thresholdlike” behavior in much the same way as corrosion potential, impurities, degree of sensitization, stress, temperature, and so forth. Other radiation phenomena, such as radiation creep relaxation and differential swelling, could also have “persistent” effects if one relies on the sources of stress present during radiation (e.g., weld residual stresses or loading from differential swelling) during postirradiation testing. The effects of radiation rapidly (in seconds) achieve a dynamic equilibrium in water, primarily because of the high mobility of species in water. In metals, dynamic equilibrium is achieved—if ever—only after many dpa, typically requiring years of exposure. While both radiation-induced segregation (RIS) of major elements, and radiation hardening (RH) and the associated microstructural development asymptotically approach a dynamic equilibrium, other factors (e.g., RIS of silicon, or precipitate formation or dissolution) may become important. Yet data on post-irradiation slow strain rate tests (SSRT) on stainless steels show that there is a distinct

(although not invariant) “threshold” fluence at which IASCC is observed under LWR conditions (Ref 8, p 583). Because this “threshold” occurs at a fraction to several dpa (depending on the alloy, stress, water chemistry, etc.) as shown in Fig. 3, in situ effects (corrosion potential, conductivity, and temperature) may be important, but only “persistent” radiation effects (microstructural and microchemical changes) can be responsible for the “thresholdlike” behavior versus fluence in postirradiation tests.

Having established the importance of persistent changes to the material in postirradiation observations of IASCC, the challenge then becomes one of identifying the specific changes in the material that accelerate SCC. These material changes fall into three categories: (a) micro-compositional effects due to radiation-induced segregation of both impurities and major alloying elements, (b) microstructural changes, such as the formation of dislocation loops, voids, precipitates, and the resulting hardening (increase in yield strength), and (c) deformation mode, including formation of dislocation channeling and localized deformation in irradiated materials. As shown by the composite schematic diagram in Fig. 4, all of the observable effects of irradiation on the material increase with dose in much the same manner, making difficult the isolation of and attribution to individual contributions. The dislocation loop microstructure is closely tied to radiation hardening, and both increase with dose until saturation occurs by approximately 5 dpa. Radiation-induced segregation also increases with dose and tends to saturate by approximately 5 dpa. Although dependent on both metallurgical and environmental parameters, IASCC generally occurs at doses between 0.5 dpa (for BWRs) and 2 to 3 dpa (for PWRs) (Ref 3), which encompasses the steeply rising portion of the curves in Fig. 4 that describe the changes in material properties with irradiation. Following a review of service experience, subsequent sections focus on the possible mechanisms by which water chemistry, RIS, microstructure, hardening, deformation mode, and irradiation creep—individually or in concert—may affect IASCC.

Fig. 3 Dependence of cracking in neutron-irradiated high-purity type 304 stainless steel (SS) on accumulated high-energy neutron fluence. IGSCC, intergranular stress-corrosion cracking

Fig. 2 Mechanistic issues believed to influence crack advance during irradiation-assisted stress-corrosion cracking (IASCC) of austenitic stainless steels.

Service Experience

An historical perspective of IASCC service experience is instructive, as the phenomenon extends back many decades, and the early observations and conclusions projected an accurate image of the important characteristics, generic nature, and broad relevance to plant components. As with other instances of environmental cracking, occasional early observations pointed the way toward a growing incidence with time and neutron fluence. First reported in the early 1960s (Ref 1, 5, 12–29), IASCC involved intergranular cracking of stainless steel fuel cladding in a PWR. The findings and conclusions were that intergranular cracking morphology pre-

Fig. 4 Composite diagram showing the increase in all parameters (RIS, dislocation loops, hardness) with dose. The IASCC response is shifted by test technique and water chemistry conditions. RIS, radiation-induced segregation; dpa, displacements per atom

dominated, with initiation of multiple cracks occurring from the waterside. By contrast, only ductile, transgranular cracking was observed in postirradiation mechanical tests performed in inert environments and at various temperatures and strain rates. Grain-boundary carbide precipitation was generally not observed by optical or transmission electron microscopy (although preexisting thermal sensitization was present in some cases). A correlation between time-to-failure and stress level was reported, with failure occurring first in thin-walled rods with small fuel-to-cladding gaps, where swelling strains were largest. The highest incidence of cracking occurred in peak heat flux regions, corresponding to the highest fluence and the greatest fuel-cladding interaction (highest stresses and strains). Similar stainless steel cladding in PWR service exhibited fewer instances of intergranular failure. At that time the PWR failures were attributed to off-chemistry conditions or stress rupture.

Irradiation-assisted SCC has since been observed in a growing number of other stainless steel (and nickel alloy) core components, such as neutron source holders in 1976 and control rod absorber tubes in 1978. Instrument dry tubes and control blade handles and sheaths (Fig. 5), which are subject to very low stresses also cracked, although generally in creviced locations and at higher fluences (Ref 30, 31). Following an initial trickle of failures in the most susceptible components, numerous incidents of IASCC have been observed since the early 1990s, perhaps most notably in BWR core shrouds (Ref 1, 5, 12, 13, 34) and PWR baffle former bolts (Ref 3, 35, 36).

Table 1 presents a broad summary of reported failures of reactor internal components, conclusively showing that IASCC is not confined to a particular reactor design. For example, stain-

less steel fuel cladding failures were reported years ago in commercial PWRs and in PWR test reactors (Ref 1, 15, 16, 22–29). At the West Milton PWR test loop, intergranular failure of vacuum annealed type 304 stainless steel fuel cladding was observed in 316 °C (601 °F) ammoniated water (pH 10) when the cladding was stressed above yield (Ref 24). Similarly, IASCC was observed in creviced 20Cr/25Ni/Nb stainless steel fuel element ferrules in the Winfrith steam-generating heavy water reactor (SGHWR), a 100 MWe plant in which light water is boiled within pressure tubes, giving rise to a coolant chemistry similar to other boiling water reactor designs (Ref 37). The 20%Cr/25%Ni/Nb stainless steel differs from type 304 primarily in nickel and niobium content, as well as in its lower sulfur (approximately 0.006%) and phosphorus (approximately 0.005%) contents. The ferrules were designed for a 5 year exposure during which the peak fast neutron flux is 2 to 3×10^{13} n/cm²·s ($E > 1.5$ MeV), yielding a peak fluence over 5 years of 3 to 5×10^{21} n/cm².

Reactor type comparisons were also made in swelling tube tests performed in the core of a BWR and a PWR on a variety of commercial and high-purity heats of types 304, 316, and 348 stainless steel and alloys X-750, 718, and 625 (Ref 38, 39). Swelling was controlled by varying the mix of aluminum oxide (Al₂O₃) and boron carbide (B₄C) within the tubes; the latter swells as neutrons transmute boron to helium. Nominally identical strings of specimens were inserted into the core in place of fuel rods. The distinction in the IASCC response between the two reactor types was small.

The oxidizing potential in a PWR core is lower than in BWRs operating in normal water chemistry (currently, many BWRs operate with catalytic surfaces and with some H₂ addition, which dramatically reduces the oxidizing

(a)

(b)

Fig. 5 Dependence of irradiation-assisted stress-corrosion cracking on fast neutron fluence for (a) creviced control blade sheath in high conductivity boiling water reactors (BWRs) (Ref 30) and (b) as measured in slow strain rate tests at 3.7×10^{-7} s⁻¹ on preirradiated type 304 stainless steel (SS) in 288 °C (550 °F) water (Ref 33). The effect of corrosion potential via changes in dissolved oxygen is shown at a fluence of $\sim 2 \times 10^{21}$ n/cm². IGSCC, intergranular stress-corrosion cracking; GB, grain boundary

potential (Ref 40–42). This led some investigators attributed PWR cracking incidents to low-ductility stress rupture (of course, this mechanism would be equally applicable to BWRs). A few laboratory studies reported small amounts of intergranular cracking of irradiated stainless steels in slow strain rate tensile tests in approximately 300 °C (570 °F) inert environments (Ref 43), although in many related experiments (Ref 32, 33) no similar evidence of intergranular cracking in inert tensile tests is not surprising; evidence against it as the sole basis for service failures includes the vastly greater extent of intergranular cracking in tests performed in high-temperature water, the general observation that crack initiation occurs from the water side, and the widespread observation that exposure to hot water produces an environmental enhancement in cracking.

Since the early 1990s, the plant and laboratory evidence of IASCC makes a compelling case that cracking is environmentally assisted and that there is a well-behaved continuum in response over ranges in fluence, corrosion potential, temperature, stress, and so forth (Ref 1, 5, 12, 13). Since there is a consistent trend toward increasing IASCC susceptibility with increasing corrosion potential in BWRs (e.g., Fig. 5b), PWRs should be less susceptible to IASCC. However, other factors distinguish PWRs from BWRs, including their higher temperatures, approximately $10\times$ higher neutron fluence in core structural components, higher hydrogen fugacity, and the borated-lithiated water chemistry (including the possibility of localized boiling and thermal concentration cells in crevices from gamma heating that could lead to aggressive local chemistries). The possible role of RIS of silicon at high fluence may be especially important in accounting for

the small effect of corrosion potential on SCC response (Ref 44), which would pose challenges for both BWRs and PWRs.

More detailed and quantitative IASCC field experience was reported by Brown and Gordon (Ref 30, 31), who accumulated and analyzed data for cracking in alloy 600 shroud head bolts (first observed in 1986), and stainless steel safe ends (first observed in 1984) and in-core instrumentation tubes (first observed in 1984), with a focus on components that were creviced, a factor known to exacerbate cracking (Ref 17, 30, 31). The highest radiation exposure occurred for the intermediate range and source range monitor (IRM/SRM) dry tubes, which contain flux monitors housed in thin-walled, annealed stainless steel tubes. Cracking initiated in the crevice between the spring housing tube and the guide plug at fluences between 0.5 and 1.0×10^{22} n/cm² ($E > 1$ MeV). Wedging stresses from the thick oxide observed in the crevice were implicated, since other (applied and residual) stresses were negligible. The primary variable from plant-to-plant is the average coolant conductivity, which correlates strongly with cracking incidence (Fig. 6a to c). Each point in Fig. 6 represents inspection results for one BWR plant, and data are normalized using reactor operating time (i.e., “percentage of components with intergranular cracks divided by the on-line exposure time”). The scatter in Fig. 6(a) was attributed to variations in fluence and specific ion chemistry, as well as limitations in the resolution of underwater visual inspection. Scatter can also result from short-term excursions in conductivity, which is not adequately reflected in the average, as identified in Fig. 6(c).

Conductivity correlations were also reported for cracking in shroud head bolts (Fig. 6c) and creviced safe ends (Fig. 6b). The strong influence of conductivity on cracking of stainless steel has also been shown in laboratory tests and plant recirculation piping, where predictive modeling (Ref 1, 5–7, 45, 46) has been compared to field data on the operational time required to achieve a detectable crack (typically 10% of the wall thickness). Preliminary

Table 1 Irradiation-assisted SCC service experience

Component	Material	Reactor type	Possible sources of stress
Fuel cladding	304 SS	BWR	Fuel swelling
	304 SS	PWR	Fuel swelling
Fuel cladding(a)	20%Cr/25%Ni/Nb	AGR	Fuel swelling
Fuel cladding ferrules	20%Cr/25%Ni/Nb	SGHWR	Fabrication
Neutron source holders	304 SS	BWR	Welding and beryllium swelling
Instrument dry tubes	304 SS	BWR	Fabrication
Control rod absorber tubes	304 SS	BWR	B ₄ C swelling
Fuel bundle cap screws	304 SS	BWR	Fabrication
Control rod follower rivets	304 SS	BWR	Fabrication
Control blade handle	304 SS	BWR	Low stress
Control blade sheath	304 SS	BWR	Low stress
Control blades	304 SS	PWR	Low stress
Plate-type control blade	304 SS	BWR	Low stress

(a) Cracking in AGR fuel occurred during storage in spent fuel pond. (b) Cracking of core internals occurred away from high neutron and gamma fluxes.

Note: SS, stainless steel; L SS, low-carbon stainless steel; BWR, boiling water reactor; PWR, pressurized water reactor; AGR, advanced gas-cooled reactor; SGHWR, steam-generating heavy water reactor.

Fig. 6 The effects of average plant water purity (measured by coolant conductivity) are shown in field correlations of the core component cracking behavior for (a) stainless steel (SS) intermediate range monitor/source range monitor (IRM/SRM) instrumentation dry tubes, (b) creviced stainless steel safe ends, and (c) creviced Inconel 600 shroud head bolts, which also shows the predicted response versus conductivity. SSC, stress-corrosion cracking; IGSCC, intergranular stress-corrosion cracking

prediction of the shroud head bolt cracking also provides reasonable agreement with observation (Fig. 6c).

Cracking has also extensively occurred in high-strength, nickel-base alloy components (Ref 1, 16) as indicated in Table 1. Many incidents occur in lower radiation flux regions (e.g., where the end-of-life fluence is below approximately $5 \times 10^{19} \text{ n/cm}^2$) such as cracking of Inconel X-750 jet pump beams in BWRs. Inconel X-750 cracking has also occurred extensively in PWR fuel hold-down springs, which attain an end-of-life fluence of 1 to $10 \times 10^{21} \text{ n/cm}^2$; this has been attributed in part to vibrational stresses. The effects of irradiation on IASCC in high-strength, precipitation-hardened nickel-base alloy components is not characterized as well as in stainless steels, although in the lower flux/fluence regions the predominant effect of radiation is probably associated with the elevated corrosion potential due to radiolysis.

Two widespread examples of IASCC are in BWR core shrouds (Ref 5, 12, 13, 34) and PWR baffle former bolts (Ref 35, 36), although susceptibility clearly exists in other areas, such as control blade components, fuel components, the BWR top guide, and so forth. Stress-corrosion cracking in the BWR core shroud occurs almost exclusively near the welds (both circumferential and vertical), and initiation is observed from both the inside (ID) and outside diameter (OD) surfaces (the shroud separates the upward core flow from the downward recirculation flow that occurs in the annulus between the shroud and the pressure vessel). This large-diameter welded "pipe" has inherent susceptibility to SCC, related primarily to weld residual stresses and weld shrinkage strains (Ref 47, 48), and cracking is observed in both low-fluence and moderate-fluence areas. The extent of the enhancement in SCC susceptibility by irradiation is limited, because while radiation hardening and radiation-induced segregation occur, radiation creep also relaxes the weld residuals stress. (Of course, radiolysis plays an inherent role, since it is the dominant source of oxidants in the entire BWR circuit, as discussed later.) Predictions indicate that if SCC does not nucleate early in life (e.g., below 0.5 dpa) from high coolant impurity levels or severe surface grinding, susceptibility decreases with fluence in the shroud welds (although many shroud welds are in very low flux areas) because of radiation-induced creep relaxation. The two-sided welding procedure (alternate welding passes on the ID and OD) produces, on average, a reasonably symmetrical residual stress profile that causes the stress-intensity factor to drop below 0 as cracks approach roughly two-thirds of the wall thickness. Thus, in many shrouds cracks do not grow through-wall, although with coincident ID and OD initiation and/or large fit-up stresses, it is possible for through-wall cracks to develop.

Extensive failures of PWR baffle bolts have occurred in the last decade (Ref 35, 36) although large plant-to-plant and heat-to-heat differences are observed. Most baffle bolts are fabricated

from type 316 stainless steel cold worked to approximately 15% to increase their yield strength. The complex baffle former structure exists in a PWR because their fuel does not have a surrounding "channel," so the baffle former structure must conform closely to the geometry of the fuel to provide well-distributed water flow. The baffle former plates are usually made from annealed material, typically type 304 stainless steel. Because of their proximity to the fuel, very high fluences can develop—up to ~80 dpa by the end of the original design life. The high gamma flux produces significant heating in the components, in some instances estimated at $+40^\circ\text{C}$ ($+104^\circ\text{F}$), especially in designs where the PWR coolant does not have good access to the bolt shank. While the heat-to-heat variations are not understood, it is clear that plants that load-follow (and therefore undergo power level changes and thermal cycles) are much more prone to baffle bolt cracking. Another aggravant is the thermal gradient and possible boiling (resulting in altered water chemistry) in the shank area of the bolt if the coolant access is restricted. However, primary factors must be the very sizeable stress relaxation that occurs early in life (e.g., during the first 5 dpa), followed by preferential radiation swelling of the annealed baffle plates over the cold-worked baffle bolts, which will cause reloading. The dynamic equilibrium between swelling and radiation creep, which determines the "reloading" stress in the bolt, is likely a complex function of local neutron flux, temperature, baffle plate geometry, composition, and other factors.

In the last decade, the number of IASCC incidents has continued to grow, and there can be no question that many components in LWRs are susceptible. Strategies to mitigate IASCC, which are discussed in the section "Mitigation Strategies" in this article, and manage IASCC (e.g., by dispositioning its impact, installing mechanical restraints to mitigate the impact of IASCC in BWR shrouds, or selectively inspecting and replacing baffle bolts) have been successful. The overall trends and correlations for IASCC can be summarized as:

- While intergranular cracks related to radiation effects on solution-annealed stainless steel were once thought to occur only at fluences above approximately $0.3 \times 10^{21} \text{ n/cm}^2$, significant intergranular cracking in BWR core shrouds over a broad range of fluences make it clear that such a distinction (a true fluence threshold) is not justified (Ref 1, 12, 13, 49). Of course, observations of SCC in unsensitized stainless steel (with or without cold work) also render untenable the concept of a threshold fluence, below which no SCC occurs. This also holds for thresholds in corrosion potential, water impurities, and so forth (Ref 5, 44, 49, 50).
- Fluence affects SCC susceptibility, but almost always in a complex fashion. Stress-corrosion cracking in BWR shrouds and PWR baffle bolts does not always correlate strongly with

fluence, one important reason for this is that radiation creep produces relaxation of the stresses from welding and in bolts.

- High stresses or dynamic strains were involved in most early incidents; however, cracking has been observed at quite low stresses at high fluences and longer operating exposure. Laboratory and field data indicate that IASCC occurs at stresses below 20% of the irradiated yield stress, and at stress intensities below $10 \text{ MPa}\sqrt{\text{m}}$ ($9.1 \text{ ksi}\sqrt{\text{in.}}$) (Ref 1, 5, 12, 13, 49, 50).
- A strong effect of corrosion potential is clear from extensive laboratory and field data. Its effect is generally consistent from low to high fluence, although the quantitative change associated with changes in potential vary. Materials prone to high-radiation-induced changes in silicon level may exhibit a very limited effect of corrosion potential (Ref 44). A true threshold potential clearly does not exist, as irradiated materials exhibit IASCC in deaerated water.
- Solution conductivity (i.e., impurities, especially chloride and sulfate) strongly affects cracking propensity in BWR water (Fig. 6). As noted by Brown and Gordon (Ref 31), this correlation applies equally to low and high flux regions and to stainless steels (Fig. 6a and b) and nickel-base alloys (Fig. 6b). Indeed, the correlation closely parallels that from out-of-core (Ref 1, 5–7, 31, 45, 46).
- Crevice geometries exacerbate cracking due primarily to their ability to create a more aggressive crevice chemistry from the gradient in corrosion potential (in BWRs) or in temperature (most relevant to PWRs).
- Cold work often exacerbates cracking (especially abusive surface grinding), although it can also delay the onset of some radiation effects.
- Increasing temperature from approximately 270 to 350°C (520 to 660°F) has an important effect on IASCC, enhancing both crack initiation and growth rate (Ref 12, 13, 50).
- Grain-boundary carbides and chromium depletion are not required for susceptibility, although furnace-sensitized stainless steels are clearly highly susceptible to cracking in-core. Chromium depletion remains a primary culprit, although its effect is most pronounced in pH-shifted environments, as can develop when potential or thermal gradients exist. The role of nitrogen, sulfur, and phosphorus, and other grain-boundary segregants is less clear.
- The fluence at which IASCC is observed is dependent on applied stress and strain, corrosion potential, solution conductivity, crevice geometry, and so forth. At sufficiently high conductivities, cracking has been observed in solution-annealed stainless steel in the field (Fig. 6a and b) (Ref 31) and in the laboratory (Ref 1, 5–7, 45, 46). Thus, while convenient in a practical engineering sense, the concept of a "threshold" fluence (or stress, corrosion potential, etc.) is scientifically

misleading (Ref 5, 12, 44, 49, 50); cracking susceptibility and morphology are properly considered an interdependent continuum over many relevant parameters.

The field and laboratory data available in the early 1980s, coupled with broader fundamental understanding of environmental cracking in hot water, led to the hypothesis that—among innumerable possible radiation effects—the most significant factors were RIS at grain boundaries, radiation hardening (elevation of the yield strength), mode of deformation, radiation creep relaxation (of constant displacement stresses, e.g., in welds and bolts), and radiolysis (elevated corrosion potential in BWRs). Other factors could also be important in some instances, such as void formation, which may also affect fracture toughness, and can produce differential swelling that produces reloading of components such as baffle bolts. These factors are addressed in the subsequent sections.

Water Chemistry

Radiolysis and Its Effect on Corrosion Potential. It is widely acknowledged that SCC susceptibility is fundamentally influenced by corrosion potential, not oxidant and reductant concentrations per se (Ref 1, 5, 12, 51). The corrosion potential is a mixed potential formed by a kinetic balance of anodic and cathodic reactions on a metal surface. In the absence of oxidants such as O_2 , H_2O_2 , and Cu ion, the H_2/H_2O reaction dominates the corrosion potential of most structural materials (and platinum), and the corrosion potential can be calculated from the thermodynamics of the H_2/H_2O reaction, which depends on pH, temperature, and H_2 fugacity.

An important distinction between BWRs and PWRs is the low H_2 concentration in BWRs, which allows the formation of radiolytic species (including oxidants). Above approximately 500 ppb ($5.6 \text{ cm}^3/\text{kg}$) H_2 , radiolytic formation of oxidants is effectively suppressed (Fig. 7a) and the corrosion potential remains close to the thermodynamic minimum as defined by the H_2/H_2O reaction. Boiling water reactors cannot achieve this H_2 level because H_2 partitions to the steam phase, which begins to form about a quarter of the way up the fuel rods. Thus, radiolysis is relevant to BWR water chemistry. There are a number of sequential and nonlinear dependencies that must be considered, for example, radiation flux versus oxidant concentration, oxidant level versus corrosion potential, corrosion potential versus crack chemistry, and crack chemistry versus SCC growth rate (Ref 5, 51).

Water is decomposed by ionizing radiation into various primary species (Ref 52–55) including both radicals (e.g., e_{aq}^- , H , OH , HO_2) and molecules (e.g., H_2O_2 , H_2), which can be oxidizing (e.g., H_2O_2 , HO_2) or reducing (e.g., e_{aq}^- , H , H_2). The predominant species that are

stable after a few seconds are H_2O_2 and H_2 , with O_2 forming primarily from the oxidation of H_2O_2 and HO_2 with an OH radical, and from the thermal decomposition of H_2O_2 . Because H_2 partitions to the steam phase and H_2O_2 is not volatile, approximately 87% of the water that is recirculated in a BWR (approximately 11 to 14% of the core flow becomes steam) is oxidant rich. Hydrogen (H_2) is introduced in the feedwater, which mixes with the recirculated water near the top of the annulus (the region of down-flow between the core shroud and pressure vessel).

The concentrations of radiolytic species are roughly proportional to the square root of the radiation flux in pure water. The radiation energy-intensity spectrum influences the concentration of each radiolytic species, which is described in terms of a yield, or G value (molecules produced per 100 eV absorbed by water). In LWRs, the G values for most species are within a factor of approximately 3 for fast neutron versus gamma radiation. Despite this similarity, the influence of fast neutron radiation is much stronger than gamma radiation primarily because the energy deposition rate, or mean linear energy transfer (LET), is greater (40 eV/nm for fast neutrons, versus 0.01 eV/nm for gamma radiation) (Ref 55). Also, the neutron flux in LWRs (e.g., $\sim 1.03 \times 10^9$ rad/h core average and $\sim 1.68 \times 10^9$ rad/h peak in a BWR of $51 \text{ W}/\text{cm}^3$ power density) is also higher than the gamma flux ($\sim 0.34 \times 10^9$ rad/h). Indeed, the moderate gamma levels present in the down-comer in the outside annulus of a BWR core actually promote recombination of hydrogen and various oxidants (Ref 53, 56). The contribution of thermal neutrons and beta particles to radiolysis is small in LWRs.

As in many electrochemical processes, the integrated effects of various oxidants and reductants on environmental cracking is best described via changes in corrosion potential, which (at constant pH and temperature) controls the thermodynamic phase stability and influences the kinetics of electrochemical reactions. Since electrochemical potentials are logarithmically dependent on local oxidant, reductant, and ionic concentrations (via the Nernst relationship, $\phi = \phi_o + RT/nF \ln [\text{products/reactants}]$), radiation-induced increases in concentration of various species by many orders of magnitude may have comparatively small effects on the corrosion potential in hot water (note: the Nernst equation is described in detail in *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, of the *ASM Handbook*). Furthermore, corrosion potentials are mixed potentials involving a balance of anodic and cathodic reactions on the metal surface, which depend on the concentrations of both oxidizing and reducing species. At low oxidant concentrations, the rapid drop in corrosion potential to approximately $-0.5 \text{ V}_{\text{SHE}}$ (Fig. 8a) results from mass transport limited kinetics (e.g., oxygen transport to the metal surface). In this regime, more pronounced shifts in corrosion potential with radiation can occur, presumably from the radiolytic formation of

oxidizing species within the mass transport limited stagnant layer.

The relationship between dissolved oxygen and corrosion potential in hot water as a function of radiation type and flux is shown in Fig. 8(a), in which the connected points represent data obtained in controlled, radiation on/off experiments. The data from these latter experiments are shown in Fig. 8(b) in terms of a radiation-induced shift in potential. The curves in Fig. 8(a) represent the scatter band for the data obtained under unirradiated conditions. Similar scatter also exists in the irradiated corrosion potential data in Fig. 8(a) and comprises contributions from both real effects and experimental error. These radiation measurements are quite complex and should involve careful qualification of the radiation resistance and thermodynamic response of reference electrodes. High radiation flux experiments were performed by Taylor (Ref 56) and Miller and Andresen (Ref 57, 58)

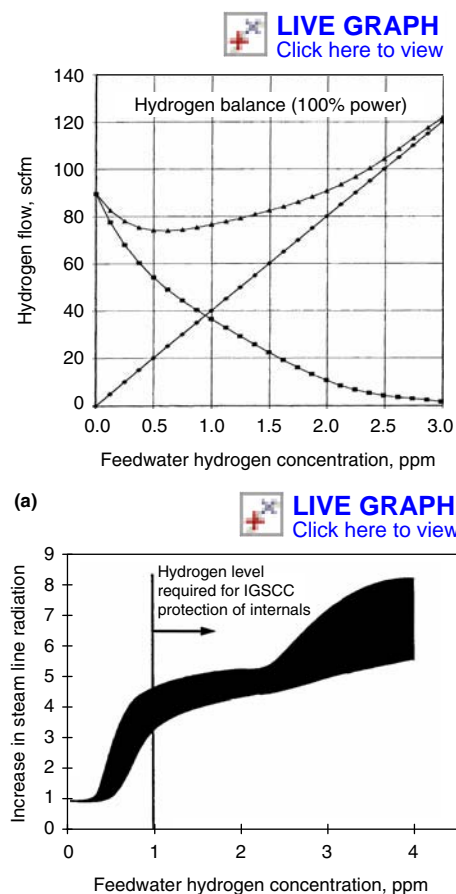

Fig. 7 (a) The relationship between the H_2 concentration in the feedwater and the H_2 injection flow (straight line, round data points). The descending curve (square data points) is H_2 generated by radiolysis, which decreases as H_2 is injected due to suppression of radiolysis. The curve that decreases and then increases (upper curve, triangle data points) is H_2 in steam. (b) The effect of H_2 injection on the radiation level in the steam lines and turbine from ^{16}N (transmuted from ^{16}O), which results in changes from soluble NO_3^- to volatile NO_x and NH_3 . IGSCC, intergranular stress-corrosion cracking

using multiple, fundamentally different types of radiation-hardened reference electrodes. In-reactor measurements have also been performed (Ref 59, 60) using multiple, radiation-qualified silver chloride reference electrodes.

Figures 8(a) and (b) show that little, if any, elevation in corrosion potential results from irradiation sources that do not include neutrons or simulate their contribution (e.g., using high-energy protons as described in Ref 57). Some studies using gamma radiation (Ref 1, 12, 57) showed a significant decrease in corrosion potential, especially in the intermediate (e.g., 10 to 200 ppb) range of dissolved oxygen. This is consistent with enhanced recombination of oxidizing and reducing species, which occurs in the downcomer region of BWRs (Ref 56) and is relied upon to produce SCC mitigation using hydrogen water chemistry (HWC). In instances where neutrons or protons have been used, a consistent, significant elevation in corrosion potential is observed. This is more pronounced in hot water containing low dissolved oxygen concentrations and no dissolved hydrogen (Fig. 8b), where increases of over $+0.25$ V occur. At higher inlet oxygen concentrations (e.g., approximately 200 ppb), the data still show a significant shift (typically $+0.1$ to 0.15 V) in corrosion potential for radiation conditions representative of peak LWR core fluxes (Fig. 8b); less increase is observed for inlet oxygen concentrations associated, for example, with air saturation (approximately 8.8 ppm O_2) or oxygen saturation (approximately 42 ppm O_2 at standard temperature and pressure, STP). A similar elevation in corrosion potential is observed for additions of hydrogen peroxide (200 ppb H_2O_2 , Fig. 8a), which suggests that H_2O_2 may be a major factor

in increasing the corrosion potential under irradiated conditions.

In-core, in situ measurements in BWRs show that the corrosion potential, which is approximately $+0.2$ to $+0.25$ V_{SHE} in normal water chemistry, can be decreased by >0.5 V by sufficient additions of dissolved hydrogen in a BWR (Ref 60). This is corroborated by other measurements (Ref 56 and Fig. 8b), which show very little radiation-induced elevation in corrosion potential when the fully deaerated inlet water contains moderate dissolved hydrogen (>200 ppb H_2 , 0 ppb O_2). However, at high H_2 levels, the core becomes reducing, and the small concentration of ^{16}N (transmuted from ^{16}O) changes from soluble NO_3^- to volatile NO_x and NH_3 , causing a large increase in radiation level in the steam lines and turbine (Fig. 7b).

The effect of radiation on the corrosion potential within a crack or crevice has also been of interest, with the possibility that a net oxidizing environment in the crack could be created that could elevate the corrosion potential above the potential at the crack mouth. In the absence of radiation, measurements in high-temperature water in artificial crevices (e.g., tubing) (Ref 61, 62), at the tip of growing cracks (Ref 63), and of short crack growth behavior (Ref 64) show that the corrosion potential remains low (i.e., -0.5 ± 0.1 V_{SHE} in 288 °C, or 550 °F, pure water) for all bulk oxygen concentrations, indicating that complete oxygen consumption occurs within the crack. Measurements of radiation effects in crevices (Ref 57) show that the elevation in corrosion potential is limited to <0.05 V ($\phi_c < -0.45$ V_{SHE}) in-core; this is consistent with interpretation of available corrosion potential data on free surfaces (Ref 1, 5, 12, 13).

These small changes will not significantly affect the approximately 0.75 V ($+0.25$ V_{SHE} {near mouth} minus -0.5 V_{SHE} {in crack}) potential difference in the crack under irradiated normal BWR water chemistry conditions. The potential difference, along with other factors, controls the enhancement mechanism that can lead to an increased anion activity and altered pH at the crack tip (Ref 6, 7, 46, 51). The crack tip pH shifts its corrosion potential (down if alkaline, up if acidic), and thereby changes the potential difference.

Effects of Corrosion Potential on IASCC. Laboratory tests have been conducted (Ref 33, 65) on preirradiated material using SSRT in hot water with additions of oxygen and/or hydrogen peroxide to elevate the corrosion potential to simulate the effect of radiation. Tests by Jacobs et al. (Ref 32) on stainless steel irradiated to $\sim 3 \times 10^{21}$ n/cm² showed a strong effect of dissolved oxygen (and, by inference, corrosion potential) on IASCC (Fig. 5b). Similarly, a variety of preirradiated materials were tested by slow strain rate (Fig. 9a), and decreasing average crack growth rates with decreasing corrosion potential were observed (Ref 65, 66). While there might be the suggestion that no IASCC occurs at low corrosion potential, in fact both crack growth rate tests (discussed later) and other tests show that IASCC persists at low corrosion potential. Figure 9(b) shows the effect of fluence and test temperature on %IGSCC of irradiated type 316 stainless steel in PWR primary water (low corrosion potential).

In situ data on fracture mechanics specimens of furnace-sensitized type 304 stainless steel exposed in Nine Mile Point Unit 1 BWR showed

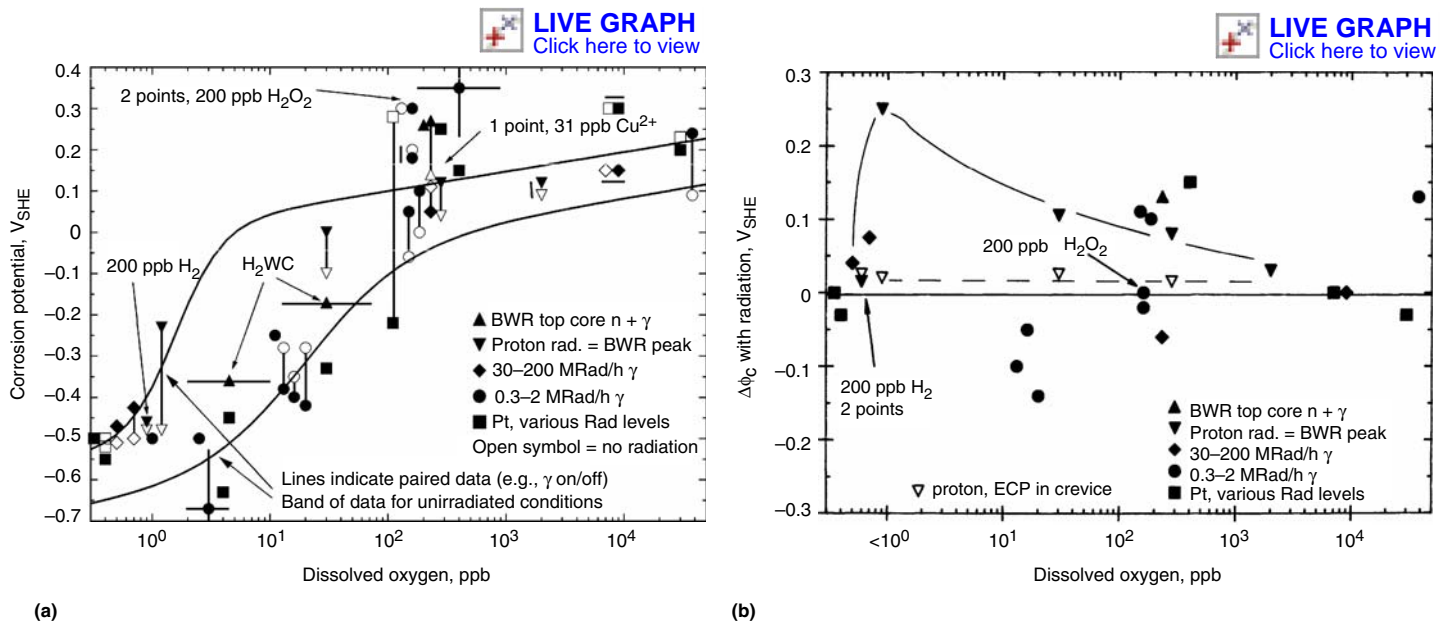

Fig. 8 (a) Effect of radiation on the corrosion potential of type 304 stainless steel in 288 °C (550 °F) water. The curves denote the range of typical values in the unirradiated corrosion potential data (Ref 1). (b) Effect of radiation on the shift in corrosion potential from the value under unirradiated conditions for type 304 stainless steel in 288 °C (550 °F) water. With the exception of the boiling water reactor (BWR) measurements, all data were obtained in controlled radiation on/off experiments (Ref 1). Curves in (b) show the trends in the proton-irradiated data, where the effects of radiation (on/off and over a range of fluxes) were evaluated for a variety of dissolved O_2 and H_2 concentrations under otherwise identical conditions.

Fig. 9 (a) Comparison of predicted and observed crack growth rates for stainless steels irradiated in a BWR at 288 °C (550 °F) to various fluences. Notched tensile specimens were tested by Ljungberg (Ref 66) at a slow strain rate in 288 °C (550 °F) pure water (Ref 1) and interrupted after a given strain/time. (b) Percentage IGSCC versus fluence for cold-worked type 316 stainless steel (SS) tested at various temperatures. Despite the low potential environment of PWR primary water, at high fluence (especially at higher temperature) there is significant susceptibility to SCC. SSRT, slow strain rate test, IGSCC, intergranular stress-corrosion cracking

that the higher corrosion potentials measured in-core versus in the recirculation piping induced significantly higher measured crack growth rates (Fig. 10). Ex situ crack growth rate testing on irradiated (4 dpa) type 304 stainless steel (Fig. 11a), shows one of many examples of well-behaved crack growth rate at high corrosion potential, along with the strong effect of reduced corrosion potential. One evolving concern for high fluence stainless steels is the prospect of a major reduction in the effect of corrosion potential and stress-intensity factor, and Fig. 11(b) shows that this is indeed observed in unirradiated alloys possessing high silicon. The detrimental effect of silicon is likely associated with its ability to oxidize at all LWR-relevant potentials

coupled with its relatively high solubility—that is, it is not a protective oxide like Cr_2O_3 or Fe/Ni oxides/spinels.

These data are compared with other irradiated and unirradiated data in Fig. 12 based on simultaneous measurements of corrosion potential and crack growth rate in fracture mechanics specimens; the accompanying curves represent model predictions (Ref 1, 5–7, 12, 13, 46, 51, 59, 66). Clearly the in situ data compare favorably with the spectrum of unirradiated data and data obtained on a fracture mechanics specimen of furnace-sensitized type 304 stainless steel using high-energy proton irradiation to simulate the mix of neutron and gamma radiation present in power reactors.

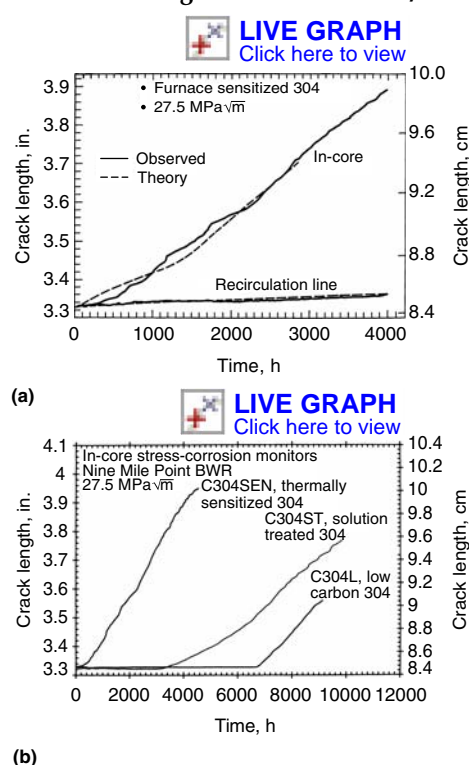

Fig. 10 Data for fracture mechanics specimens of type 304 stainless steel exposed in the high flux region of the core and in the recirculation line of Nine Mile Point Unit 1 Boiling Water Reactor (BWR). All specimens were precracked and wedge loaded to an initial stress-intensity factor of $\sim 27.5 \text{ MPa}\sqrt{\text{m}}$ ($\sim 25 \text{ ksi}\sqrt{\text{in.}}$). (a) Comparison of predicted and observed crack length versus time for furnace-sensitized type 304 stainless steel specimens in the core and recirculation line. (b) Crack length versus time for a furnace-sensitized and two annealed specimens of type 304 stainless steel in the core. Source: Ref 1, 6, 12, 13, 59

Radiation-Induced Segregation

Radiation-induced segregation is a common phenomenon in irradiated alloys and describes the redistribution of major alloying elements and the enrichment or depletion of impurity elements at point defect sinks (Ref 67–76). By virtue of their susceptibility to IGSCC, the sinks of greatest interest are the grain boundaries. Radiation-induced segregation is driven by the flux of radiation-produced defects to sinks and is therefore fundamentally different from thermal segregation or elemental depletion due to grain-boundary precipitation processes. Vacancies and interstitials are the basic defects produced by irradiation and can reach concentrations that are orders of magnitude greater than the thermal equilibrium concentrations. Diffusion of solutes by vacancy or interstitial mechanisms (inverse Kirkendall) is accelerated by the elevated concentration of these defects. If the relative participation of alloying elements in the defect fluxes is not the same as their relative concentration in the alloy, then a net transport of the constituents to or from the grain boundary will occur (Fig. 13). This unequal participation of solutes in the vacancy and/or interstitial fluxes to sinks

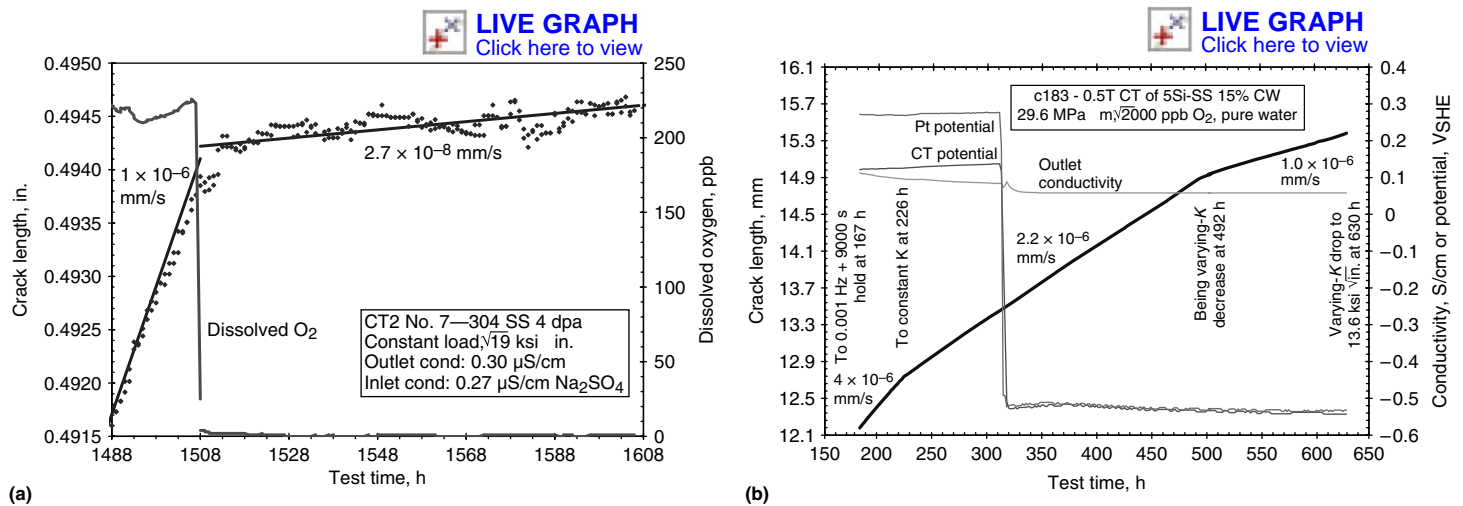

Fig. 11 (a) Crack length versus time for type 304 stainless steel irradiated to 4 dpa in a boiling water reactor showing the elevated crack growth rates at high corrosion potential, but significant decrease in growth rate as the corrosion potential is decreased. These data are plotted as large triangles on Fig. 12. (b) Crack length versus time for a custom "stainless steel" representative of the composition of an irradiated grain boundary, notably containing high silicon. There is no effect of the change in corrosion potential, nor an effect from decreasing stress intensity (K) from 29.6 to 14.3 MPa $\sqrt{\text{m}}$ (27 to 13 ksi $\sqrt{\text{in.}}$). While the crack growth rate response of such a bulk alloy cannot be presumed to be representative of an irradiated material, these data and other data on type 304L stainless steel possessing 3 or 1.5% Si show broadly similar behavior.

Fig. 12 Observed and predicted relationships of crack growth rate versus corrosion potential for furnace-sensitized type 304 stainless steel (SS) at a constant stress intensity (K) of ≈ 27.5 MPa $\sqrt{\text{m}}$ (25 ksi $\sqrt{\text{in.}}$). The observed data were obtained in water of conductivity between 0.1 to 0.3 $\mu\text{S}/\text{cm}$. The predicted relationships show the sensitivity of the crack growth rate to changes in combinations of corrosion potential and water purity (0.1 to 0.5 $\mu\text{S}/\text{cm}$) (Ref 5-7, 46, 47). The large triangles were obtained on type 304 stainless steel irradiated to 4 dpa. The larger circles and rectangles represent cold-worked stainless steel and Alloy 600.

results in either enrichment or depletion of an alloying element at the grain boundary. The species that diffuse more slowly by the vacancy diffusion mechanism are enriched, and the faster diffusers become depleted. Enrichment and depletion can also occur by association of the solute with the interstitial flux. The undersized species will enrich, and the oversized species will deplete (Ref 69). The magnitude of the buildup/depletion is dependent on several factors such as whether a constituent migrates more rapidly by one defect mechanism or another, the binding energy between solutes and defects, the dose, dose rate, and the temperature. The RIS profiles are also characterized by their narrowness, often confined to within 5 to 10 nm of the grain boundary, as shown in Fig. 14 for an irradiated stainless steel.

Segregation is a strong function of irradiation temperature, dose, and dose rate. Segregation peaks at intermediate temperatures since a lack of mobility suppresses the process at low temperatures, and back-diffusion of segregants minimize segregation at high temperature (where defect concentrations approach their thermal equilibrium values). For a given dose, lower dose rates result in greater amounts of segregation (at LWR temperatures). At high dose rates, the high defect population results in increased recombination that reduces the number of defects that are available to diffuse to the grain boundary. Figure 15 shows the interplay between temperature and dose rate for an austenitic stainless steel. Radiation-induced segregation occurs in the intermediate temperature range, and this range rises along the temperature scale with increasing dose rate to compensate for the higher recombination rate.

In the Fe-Cr-Ni alloy system, studies have shown that nickel segregates to grain boundaries while chromium and iron deplete. The directions of segregation are consistent with an atomic

Fig. 13 Inverse Kirkendall effects induced by (a) vacancy flux, (b) interstitial flux, and (c) and (d) the effect of diffusion coefficients on the depth distribution for A atoms in an AB alloy. J, C, and D refer to the flux, concentration, and diffusion coefficient, respectively, of diffusing species defined by the subscript, by way of the complementary species defined by the superscript (V, vacancies, I, interstitials). Source: Ref 68

Fig. 14 Typical segregation profiles in commercial purity type 304 stainless steel irradiated to $\sim 10^{22}$ n/cm² at 275 °C (525 °F). Composition profiles were measured using a field emission gun scanning transmission electron microscope (FEGSTEM). Source: Ref 72

volume effect in which the sub-sized solute migrates preferentially with the interstitial flux, and the oversized solute participates preferentially in the vacancy flux. The results are also consistent with the diffusivity of the solutes in Fe-Cr-Ni, in which nickel is the slow diffuser, chromium is the fast diffuser, and iron is intermediate. While the inverse Kirkendall mechanism involves preferential association of solutes with both vacancy and interstitials, the observed major element segregation in Fe-Cr-Ni alloys

can be qualitatively and quantitatively accounted for by only vacancy exchange, indicating that for this system, preferential participation of solutes by interstitials is not required (Ref 73, 74).

While chromium depletes at grain boundaries and nickel enriches across a wide range of composition in the austenitic Fe-Cr-Ni alloy system, iron can either deplete or enrich according to the magnitude of the diffusion coefficient relative to the other solutes (Ref 77). Allen et al. (Ref 73) showed that iron segregation compensates for

Fig. 15 Dependence of radiation-induced segregation on homologous temperature and dose rate for austenitic stainless steels. LWR, light water reactor

the differences in relative diffusivities and abundances of chromium and nickel. Iron is observed to deplete in most austenitic stainless steel alloys and nickel-base alloys, but it can enrich if the ratio of bulk nickel to bulk chromium is very low. Radiation-induced segregation increases with neutron dose in LWRs and saturates after several (~ 5) dpa in the 300 °C (570 °F) temperature range. Figure 16 shows grain-boundary chromium depletion for austenitic stainless steels as a function of dose. As the slowest diffusing element, nickel becomes enriched at the grain boundary. Since iron depletes in 304 and 316 stainless steels, the nickel enrichment makes up for both chromium and iron depletion and can reach very high levels, up to ~ 30 wt%. For all of the major elements, the segregation profile is very narrow, generally between 5 and 10 nm full width at half maximum (FWHM). The narrow profile and limitations of the analysis technique makes exact measurements of the grain-boundary values difficult and knowledge of the true grain-boundary compositions is aided by the use of segregation models (Ref 86, 87).

Heat treatment of stainless steels prior to irradiation will often result in an enrichment of chromium at the grain boundary. Subsequent irradiation eventually leads to grain-boundary chromium depletion, but an intermediate step involves the formation of a W-shaped profile

Fig. 16 Dose dependence of grain-boundary chromium concentration for several 300-series austenitic stainless steels irradiated at a temperature of about 300 °C (570 °F). Source: Ref 78–86

Fig. 17 Variation of the grain-boundary (GB) chromium concentration profile in commercial-purity type 304 stainless steel with dose for 3.2 MeV proton irradiation at 360 °C (680 °F). Source: Ref 86

at low dose. The W-shape is due in part to the initial chromium enrichment. However, inverse Kirkendall-based calculations of grain-boundary composition under irradiation show that the W-shape should transform to a V-shaped depletion profile for doses beyond 0.1 dpa, when in fact, observations show (Ref 86) that it tends to persist beyond 1.0 dpa (Fig. 17).

The source of the tenacity of the W-shape profile may be cosegregation of solutes such as molybdenum or impurities such as carbon or boron. Enrichment of boron, carbon, and phosphorus at grain boundaries in 304 stainless steel has been measured in the unirradiated case (Ref 88). There was a pronounced affinity between molybdenum and nitrogen noted as well, leaving open the possibility that interstitial impurities may play a role in the persistence of the W-shaped profile under irradiation.

Minor alloying elements and impurities also segregate and have been implicated in the IASCC process as well. Manganese and molybdenum strongly deplete at the grain boundary under irradiation (Ref 85). Manganese is a minor alloying element in 304 and 316 stainless steels. As a fast diffuser, it depletes rapidly with dose in preference to chromium. Molybdenum is added to 316 stainless steel to improve pitting resistance, and as an oversized element it also depletes rapidly at the grain boundary. Other minor alloying or impurity elements such as silicon and phosphorus also segregate under irradiation. Silicon strongly enriches at the grain boundary to as much as 10 times the bulk (0.7 to 2.0 at.%) composition in the alloy (Ref 89). However, the γ' phase has not been observed at the grain boundary even in cases where the silicon concentration is well above the solubility limit. Phosphorus is present at much lower concentrations and is only modestly enriched at the grain

boundary due to irradiation (Ref 72, 85). Phosphorus tends to segregate to the grain boundary following thermal treatment, which reduces the amount of additional segregation to the grain boundary during irradiation, making the contribution due to irradiation difficult to detect (Ref 85). Undersized solutes such as carbon, boron, and nitrogen should also segregate, but there is little evidence of RIS, due in part to the difficulty of measurement. Another potential segregant is helium, produced by the transmutation of ^{10}B . The mobility of helium is low at LWR core temperatures, but the opportunity for accumulation at the grain boundary is increased by segregation of boron to the boundary. Overall, the behavior of these minor elements under irradiation is not well understood.

Significant work has occurred recently on the effect of oversized solutes on IASCC. These solutes may affect the microchemistry or microstructure of the alloy, thereby altering the IASCC susceptibility. Oversized solutes are believed to affect RIS by acting as vacancy traps, thereby increasing the effective recombination of vacancies and interstitials and thus reducing RIS. Kato et al. (Ref 90) conducted electron irradiations of several stainless steels at temperatures of 400 to 500 °C (750 to 930 °F) up to 10 dpa. Among the solutes added to the reference alloy were titanium, niobium, vanadium, zirconium, tantalum, and hafnium. Results showed that some solutes (zirconium and hafnium) consistently produced a large suppression of radiation-induced chromium depletion, while others resulted in less suppression or suppression at only certain temperatures (Fig. 18). Fournier et al. (Ref 91) conducted irradiation of type 316 stainless steel containing hafnium or platinum

using 3 MeV protons (400 °C, or 750 °F) or 5 MeV nickel ions (500 °C, or 930 °F). Nickel irradiations showed little effect of the oversized impurity in reducing grain-boundary chromium depletion (chromium depletion increased in the case of hafnium), but proton irradiation showed a significant suppression of RIS of chromium at low dose (2.5 dpa) with the effect diminishing at higher (5.0 dpa) dose. Platinum had a smaller effect on chromium. Titanium and niobium similarly produced little change in the grain-boundary chromium concentration after irradiation with 3.2 MeV protons to 5.5 dpa at 360 °C (680 °F). In zirconium-doped type 304 stainless steel, there were no consistent results of suppression of grain-boundary chromium after 3.2 MeV proton irradiation to 1.0 dpa at 400 °C (750 °F) (Ref 93). In all, the data on the effect of oversized solutes on RIS of chromium are very inconsistent.

Radiation-induced segregation is often implicated in IASCC of stainless steels, especially in oxidizing environments, due to the wealth of data from laboratory and plant operational experience with sensitized components (Ref 3, 4, 12, 31, 34, 94, 95). As shown in Fig. 16, grain-boundary chromium depletion during irradiation can be severe. Figure 19(a) shows a correlation between grain-boundary chromium level and IGSCC susceptibility in stainless steels where the grain-boundary depletion is due to sensitization (Ref 96). Much data have been accumulated to support the role of chromium depletion as an agent in IGSCC of austenitic alloys in oxidizing conditions. Numerous studies show that as the grain-boundary chromium level decreases, IGSCC increases. Typical chromium-depleted zone widths are of the order of 100 to 300 nm

Fig. 18 Effect of oversize solute on the grain-boundary chromium concentration following irradiation with electrons (Ref 90), protons (Ref 91), and neutrons (Ref 92)

FWHM, providing a significant volume of depleted material adjacent to the grain boundary.

Figure 19(b) shows a similar correlation between grain-boundary chromium level and IASCC susceptibility as measured by the percentage of intergranular cracking (%IG) cracking on the fracture surface during SSRT experiments. A major difference between chromium-depletion profiles resulting from RIS and those due to precipitation reactions is that the width of the RIS profiles can be as much as two orders of magnitude smaller, or 5 to 10 nm. There is also a tremendous amount of scatter in the data of Fig. 19(b) that makes a direct correlation difficult to support. In particular, at low grain-boundary chromium levels, the %IG ranges from 0 to 100. However, as the grain-boundary chromium content increases, the data become less “noisy,” suggesting that a higher grain-boundary chromium concentration is a strong indicator of resistance to IASCC. Also, there is a trend in the maximum level of %IG with grain-boundary chromium content. There-

fore, one interpretation of these data is that grain-boundary chromium depletion is an *important*, but *insufficient* condition for IASCC to occur.

Additional data to support the idea that factors other than grain-boundary chromium depletion are important in IASCC come from the growing number of experiments on postirradiation annealing. Busby et al. (Ref 98) showed that the different rates at which RIS and dislocation loops anneal during a postirradiation heat treatment creates a window in time-temperature space in which annealing of the dislocation loop structure can occur to a great extent with little change in the grain-boundary composition profile. Several studies have been conducted on the postirradiation annealing of irradiated stainless steels and the assessment of the IASCC susceptibility as a function of annealing time and temperature (Ref 99–102) and all show that the grain-boundary chromium concentration remains at the as-irradiated level well beyond the point where the IASCC susceptibility has been substantially reduced. This occurrence is another indication that while RIS may be an important factor in IASCC, it does not alone explain IASCC.

Recent experiments by Allen et al. (Ref 102) and Was et al. (Ref 103) on stainless steels with chromium preseggregation provide additional perspective on the role of chromium. In these experiments, several alloys were given a chromium-enrichment heat treatment of 1100 °C (2010 °F) for 20 min followed by air cooling. Grain-boundary chromium enrichment is believed to occur by a thermal, nonequilibrium segregation process (Ref 104). Results of subsequent irradiations showed that despite higher measured grain-boundary chromium concentrations, IASCC susceptibility was no better, and often worse, than when starting without chromium preenrichment (Fig. 20). These data cast further doubt on the sufficiency of grain-boundary chromium depletion as the key factor in IASCC even in oxidizing media.

Fig. 19 Effect of grain-boundary (GB) chromium content on intergranular stress-corrosion cracking (IGSCC) for (a) sensitized stainless steel (SS) and alloy 600 (Source Ref 96) and (b) irradiated stainless steels. SSR, slow strain rate.

Fig. 20 Effect of chromium enrichment heat treatment on irradiation-assisted stress-corrosion cracking in constant extension rate test in simulated BWR normal water chemistry at 288 °C (550 °F). Source: Ref 102, 103

Under irradiation, both molybdenum and manganese deplete at the grain boundary, but neither is believed to be a significant factor in IASCC. Among the minor alloy elements, only silicon is observed to segregate to high levels and silicon segregation is correlated with IASCC. Experiments by Busby et al. (Ref 97) on a high-purity 316 base alloy doped with 1 wt% Si showed severe IASCC in normal water chemistry and in primary water after proton irradiation to 5.5 dpa at 360 °C (680 °F). Scanning transmission electron microscopy (STEM) measurements of grain-boundary silicon confirm levels up to 6 wt%. Past studies comparing Auger electron spectroscopy (AES) and STEM results have shown that the actual concentration of silicon at the grain-boundary plane may be as high as 15 to 20 wt%. Though the electron beam probe in STEM is very small, the measurement underpredicts the concentration at the grain boundary by as much as a factor of 3. Yonezawa et al. (Ref 105–108) and Li et al. (Ref 109) have provided extensive evidence to show that increased silicon in stainless steel results in increased IGSCC in alloys tailored to imitate the composition of grain boundaries under irradiation. However, it should be noted that these alloys were not irradiated, and this difference may be important in the relevance of such experiments to IASCC. Using 1.5 to 5% Si stainless steels of both standard (e.g., 304L) base composition and synthetic irradiated grain-boundary composition, Andresen has observed (Fig. 11b) significantly increased growth rates, a reduced benefit of a lower corrosion potential, and very little effect of stress-intensity factor between 30 and 14 MPa \sqrt{m} (27 and 13 ksi $\sqrt{in.}$).

The data on impurity segregation effects on IASCC remain inconclusive. Extensive experiments have been conducted to isolate the effect of particular impurities such as silicon, phosphorus, carbon, nitrogen, and boron in IASCC, but none have yielded unambiguous results. Sulfur has not been found to segregate under irra-

diation, and while phosphorus thermally segregates to a significant extent, irradiation-induced phosphorus segregation is small in comparison. Carbon, nitrogen, and boron cannot be measured in STEM, nitrogen and boron are very difficult to identify in AES, and carbon is a common contaminant. Overall, it has been a challenge to establish a link between impurity-element segregation and IASCC in austenitic stainless steels.

Microstructure, Radiation Hardening, and Deformation

Irradiated Microstructure. The microstructure of austenitic stainless steels under irradiation changes rapidly at LWR service temperatures. Point defect clusters (“black dot damage”) form at very low dose, dislocation loops and the network dislocation density evolve with dose over several dpa, and the possibility exists for the formation and growth of helium-filled bubbles, voids, and precipitates in core components in locations exposed to higher dose and temperatures. Typical radiation-induced microstructural features in austenitic stainless steels are dislocation loops, network dislocations, cavities (bubbles and/or voids), and precipitates (Ref 110–116). The microstructure is quite sensitive to temperature with a transition occurring in the 300 °C (570 °F), range. Below 300 °C (570 °F), the microstructure is dominated by small clusters and dislocation loops. Near 300 °C (570 °F), the microstructure contains larger faulted loops plus network dislocations from loop unfaulting and cavities at higher doses. Figure 21 summarizes the types of defect structures reported in 300-series stainless steels as a function of irradiation temperature and dose of relevance to the LWR regime.

Under LWR conditions, the dominant defect structures by far are vacancy and interstitial clusters and Frank dislocation loops. The defect

clusters may be of vacancy or interstitial type and are formed as a result of the collapse of a damage cascade during irradiation. The larger, faulted dislocation loops nucleate and grow as a result of the high mobility of interstitials. The loop population grows in size and number density until absorption of vacancies and interstitials equalize, at which point the population has saturated. Figure 22 shows the evolution of loop density and loop size as a function of irradiation dose during LWR irradiation at 280 °C (535 °F). Note that saturation of loop number density occurs very quickly, by ~1 dpa, while loop size continues to evolve up to ~5 dpa. The specific number density and size are dependent on irradiation conditions and alloying elements, but the loop size rarely exceeds 20 nm and densities are of the order of $1 \times 10^{23} \cdot m^{-3}$.

Small defects may be important in the hardening process and in how they affect IASCC. It is generally believed that the small defect clusters are predominantly faulted interstitial loops and vacancy clusters (Ref 117). However, analysis of recent postirradiation annealing experiments by Busby et al. (Ref 118) and Simonen et al. (Ref 119) showed that this description may be inaccurate. Evidence suggests that there are at least two types of defects with different annealing characteristics: vacancy and interstitial faulted loops. Hardness as a function of annealing time shows a stepped behavior that is likely caused by different annealing kinetics of vacancy and interstitial loops. Annealing experiments indicate that the density of vacancy loops is perhaps much higher than previously believed, and higher than the density of interstitial loops (Ref 118).

At temperatures above 300 °C (570 °F), voids and bubbles may begin to form, aided by the increased mobility at the higher temperature. The dislocation structure will evolve into a network structure as larger Frank loops unfault. The reduction in the sink strength of the dislocation loops aids in the growth of voids and bubbles. While their size and number density increase with temperature, the dislocation microstructure continues to be the dominant microstructure component over the temperature range expected for LWR components (<350 °C, or 660 °F).

Fig. 22 Measured change in density and size of interstitial loops as a function of dose during LWR irradiation of 300-series stainless steels (SS) at 275 to 290 °C (525 to 555 °F). Source: Ref 85

Irradiation can also accelerate or retard the growth of second phases, modify existing phases, or produce new phases. A key factor in phase formation in austenitic stainless steels under LWR operating conditions is RIS. The RIS of both major and minor elements to sinks under irradiation can induce the formation of phases by exceeding the solubility limit locally. Was et al. (Ref 120) irradiated a high-purity stainless steel containing 1 wt% Si with 3.2 MeV protons to 5.5 dpa at 360 °C (680 °F). They observed the formation of γ' (Ni_3Si) in the matrix but not on the grain boundary. The same was observed in a similar alloy irradiated with neutrons to 7 dpa at 300 °C (570 °F) (Ref 72). Gamma prime is a coherent precipitate that can significantly strengthen the matrix and has the potential to alter the deformation behavior in the unirradiated and irradiated conditions. The occurrence of γ' in the matrix and not on the grain boundary is puzzling since the grain-boundary concentration of silicon is likely greater than 10 or 15% at.% in the boundary plane and the nickel concentration is also enriched. However, most of the effects of irradiation on phase formation and stability do not occur below 370 °C (700 °F). In stainless steels, the principal second phase is chromium carbides, which are stable under irradiation. In high-strength nickel-base alloys, the second phases can undergo several types of transformations. Gamma prime can dissolve, γ'' can dissolve and re-precipitate, and Laves phase can become amorphous under irradiation at LWR operating temperatures. Hence, for these alloys, moderate temperature irradiation can induce important phase changes.

Oversize solutes can also affect the irradiated microstructure by mechanisms similar to those that affect grain-boundary segregation. In both proton and nickel ion irradiations, the addition of hafnium to a type 316 stainless steel base alloy increased loop density, decreased loop size, and eliminated voids (Ref 91). Platinum addition to type 316 resulted in no change in loop density and a small increase in loop size, but increased void size and density. The good agreement between proton and nickel ion irradiation results indicates that the major effect of the oversized solute is not due to the cascade (where there are large differences between proton and nickel ion irradiation), but rather is due to the postcascade defect partitioning in the microstructure evolution. Electron irradiation experiments by Watanabe et al. (Ref 121) and proton irradiation experiments by Was et al. (Ref 120) showed that stainless steel with titanium additions had slightly lower dislocation loop densities and larger sizes compared to the base alloy. Niobium increased loop size only. In contrast to the base alloy, neither the titanium- nor the niobium-doped alloys formed voids under the conditions tested. Zirconium addition to type 304 stainless steel resulted in reduced hardness, decreased loop density, and no change in loop size in proton irradiation to 1.0 dpa at 400 °C (750 °F) when compared to the base alloy (Ref 93). Zirconium-containing samples also had a lower void density

with no change in void size as compared to the base alloy.

Irradiation Hardening. A consequence of the formation of the dislocation loop microstructure is hardening of the alloy. The dislocation loops interact elastically with the dislocation network under an applied stress, producing an increase in the yield strength of the alloy. The increase in yield strength is measurable in either a tensile test or by indentation hardness measurement. Accompanying an increase in hardness is a decrease in the ductility and fracture toughness. The yield strength increase with dose in 300-series stainless steels irradiated around 300 °C (570 °F) is plotted in Fig. 23. Note that the yield strength can reach values up to five times the unirradiated value by about 5 dpa. The increase in yield strength follows a square root dependence on dose. Various models have attempted to link the hardening behavior with the dislocation microstructure. Both the source hardening model (Ref 129) and the dispersed barrier hardening model (Ref 130) provide reasonable correlations between hardening and the dislocation loop microstructure. In the dispersed barrier hardening model, the increase in hardness is proportional to $(N_{\text{loop}} \times d_{\text{loop}})^{1/2}$, where N_{loop} is the loop number density and d_{loop} is the loop diameter.

In addition to hardening with increasing dose, the deformation mode changes dramatically. Homogeneous deformation at low dose is replaced by heterogeneous deformation at higher doses as the defect microstructure begins to impede the motion of dislocations. Plasticity becomes localized to narrow channels that have been cleared of defects by preceding dislocations, providing a path for subsequent dislocation motion. The channels are very narrow (< 10 nm) and closely spaced (< 1 μm) and typically run the full length of a grain, terminating at the grain boundaries (Ref 131). Dislocation channeling results in intense shear bands that can cause localized necking and a sharp reduction in uniform elongation (Ref 132). As discussed later, these dislocation channels may be an important factor in IASCC.

Hardening has also been cited as a key factor in IASCC susceptibility. Figures 12 and 24(a) show that increasing cold work results in increases in the crack growth rate in nonsensitized austenitic stainless steel tested in 288 °C (550 °F) BWR normal water chemistry (Ref 133). Increasing yield strength resulting from cold work is a fairly good predictor of cracking susceptibility. This dependence also carries over to irradiated material. As shown in Fig. 24(b), increased yield strength due to irradiation results in increased susceptibility to IASCC as measured by the %IG in SSRTs. Note that the correlation is quite good at both high values of yield strength (> 800 MPa, or 116 ksi) and at very low values (< 400 MPa, or 58 ksi), with more scatter at intermediate values (400 to 800 MPa, or 58 to 116 ksi). The parallel between the effects of cold work and irradiation on IASCC suggests that hardening, irrespec-

tive of its nature, is a key factor in IGSCC susceptibility.

Several pieces of evidence suggest that hardening alone is not sufficient to explain IASCC. The annealing experiments shown in Fig. 25 also tracked the change in hardness and dislocation loop microstructure versus annealing condition (Ref 134). Figure 25 shows the change in hardness and the change in the dislocation loop line length

($N_{\text{avg}} \times d_{\text{avg}}$) along with the change in IASCC susceptibility as annealing progresses, as measured by several authors (Ref 101, 116, 135). Note that except for very short annealing times, the loop line length and the hardness track each other extremely well, as would be expected if the loop structure is controlling the hardening. At very small values of $(Dt)^{1/2}$, the hardening remains flat before proceeding downward with increased annealing. While both hardening and cracking are reduced with increased annealing, the behavior of the hardness cannot fully explain the rapid and complete reversal in IASCC susceptibility with annealing condition. In particular, the cracking susceptibility changes dramatically before the hardness begins to drop from its as-irradiated value, as indicated by the plateau at low $(Dt)^{1/2}$.

Busby et al. (Ref 118) have postulated that the removal of very small defects at short annealing times may be responsible for the change in IASCC behavior. Short times at high temperature (500 °C, or 930 °F) may preferentially remove the small defect clusters either by annihilation or by spontaneous dissociation. The dislocation loops may absorb the free vacancies and interstitials, thus adding to their line length. The loss of the small defect clusters will be offset by the growth of Frank loops producing no net change in measured hardness or yield strength. Despite a lack of hardness change, this process may alter the deformation mode at the local level by removing the small obstacles to dislocation motion, thus changing the character of localized deformation that may affect IASCC.

A set of experiments conducted by Hash et al. (Ref 136) provide supporting evidence that hardening is not the sole factor in IASCC. Hash made a series of samples of commercial purity

type 304 stainless steel with nominally the same hardness, but with different contributions from cold work and irradiation. At the extremes were a sample that was cold rolled to a 35% reduction in thickness and no irradiation and one with 1.67 dpa irradiation and no cold work. Three samples had varying amounts of cold work (10%, 20%, and 25%) and corresponding amounts of irradiation dose (0.55, 0.25, and 0.09 dpa) to result in a nominally constant hardness level that varied by no more than 5% over the five samples. Stress-corrosion cracking susceptibility was measured by the amount of IG cracking in a constant extension rate test in 288 °C (550 °F) simulated BWR water with normal water chemistry. Results showed that the IASCC susceptibility was not constant, as would be expected if hardness were the only factor. Rather cracking occurred for only the two highest dose samples (0.55 dpa with 10% cold worked and 1.67 dpa with no cold worked), irrespective of their hardness (Fig. 26). The amount of cracking in the lower dose sample was higher than that in a companion sample at the same dose but without cold work (not shown), indicating that cold work can enhance the IASCC susceptibility. These results also suggest that hardening by irradiation may promote crack initiation. Nevertheless, this result along with the annealing results suggests that the microstructure itself and not just the hardness level play a role in the IASCC process.

Deformation Mode. Results of IASCC experiments on proton-irradiated samples over a wide range of doses and alloys have consistently shown that high-nickel alloys have high IASCC resistance in SSRT. In particular, nickel concentrations ≥ 18 wt% are highly resistant to

IASCC compared to type 304 stainless steel with 8 wt% Ni. Figure 27 shows existing literature data on IASCC versus nickel equivalent (Ni_{Eq}) as determined from correlations by Kodama et al. (Ref 140). It shows that there is a good, but not perfect correlation between Ni_{Eq} and IASCC. Notable exceptions are alloy 800 (Ref 144) and a Fe-20Cr-25Ni-1Nb alloy used in advanced gas-cooled reactors (AGRs) that experienced IGSCC (Ref 145). While nickel may affect IASCC directly through a change in composition, it may also affect IASCC indirectly through a change in the slip character. Higher nickel content in stainless steel increases the stacking fault energy (SFE) significantly. The increased SFE results in a change in the nature of slip from planar to wavy. Swan et al. (Ref 146) conducted a study on the effect of SFE on slip behavior of a series of Fe-18Cr-xNi alloys where $8 < x < 23$. They showed that for the 8% Ni alloy, the slip was entirely planar and as nickel increases, cross slip increases. By 20% Ni, there was no evidence of planar slip and the deformation microstructure consisted of a web of dislocation tangles, evident of wavy slip in a high SFE material. The process is shown in the micrographs and schematics in Fig. 28 in which planar slip is likely to result in greater dislocation interaction with grain boundaries than is wavy slip.

Stacking fault energy has been linked to SCC resistance in stainless steels by Thompson and Bernstein who found that increasing SFE correlates well with increased reduction in area and decreased SCC susceptibility (Ref 147). The IASCC susceptibility of several irradiated stainless steels is plotted as a function of SFE in Fig. 29 and shows that there is a good correlation between SFE and IASCC using Rhodes's (Ref 148) and Schramm's (Ref 149) correlations for SFE. These correlations differ in the elements included and the weights given to each element in terms of Ni_{Eq} . The correlations are also unable to account for several of the minor elements and therefore may deviate substantially from the true SFE in cases where minor elements carry high weight (such as silicon). Note that there is much scatter in both these plots and the plot for Ni_{Eq}

Fig. 25 Removal of radiation-induced segregation (RIS), dislocation microstructure as measured by loop line length and hardness with extent of annealing as measured by $(Dt)^{1/2}$ for iron, to account for annealing at different times and temperatures. Fig. 26 Degree of irradiation-assisted stress-corrosion cracking in type 304 stainless steel samples with the same hardness but with different combinations of hardening by cold work (CW) and irradiation using 3.2 MeV protons at 360 °C (680 °F). Source: Ref 136

and of a similar degree to that shown in the IGSCC dependence on grain-boundary chromium and yield strength. One potential source of the scatter is the inherent variability in initiation-dominated phenomena. Another is that while grain-boundary chromium and yield strength are measured, Ni_{Eq} and SFE are calculated quantities with considerable uncertainty. So while they

may be useful in identifying transitions in behavior, their reliability in quantifying alloy behavior may be much less.

The significance of the SFE is that it controls the deformation mode of the alloy. However, the microstructure can also influence the deformation mode. Farrell et al. (Ref 150) conducted neutron irradiation of type 316 stainless steel at

temperatures between 65 and 100 °C (150 and 212 °F) to doses of less than 1 dpa and characterized the deformation behavior as a function of irradiation condition. They found that with increasing dose, the propensity for dislocation channeling increased. A plot of the evolution of the dislocation microstructure and the extent of channeling as determined by the channel area is shown in Fig. 30. Note that the volume of material occupied by channels increases rapidly with dose and saturates at less than 0.5 dpa. These data are important evidence because they show that, in addition to SFE, the defect microstructure created by irradiation can induce planar deformation in the form of narrow dislocation channels. Slip planarity is the common feature between the effect of SFE and irradiation.

The importance of slip localization in IASCC may be in the way in which the dislocations interact with the grain boundary. In planar slip, well-defined and separated slip bands or dislocation channels (for irradiated materials) transmit dislocations during plastic deformation. These slip bands or channels terminate at grain boundaries where dislocations are fed into the grain-boundary region versus the buildup of a tangled dislocation network within the grain. One of two processes could occur to cause grain-boundary cracking. In the more traditional view of dislocation infusion into grain boundaries, the pileup of dislocations in the intersecting channel creates progressively higher stresses at the grain boundary at the head of the pileup. If the stress exceeds a critical value, separation of the grain boundary could occur according to a Stroh (wedge) cracking type of mechanism. This cracking process could occur regardless of the environment and may in fact be the mechanism that occurs in some of the IG cracking observed in very highly irradiated steels in inert environment (Ref 132). At lower fluences, the stress at the grain boundary may cause a rupture of the oxide film, leading to exposure of the metal to the solution and subsequent corrosion and IASCC.

Alternatively, IASCC could occur by deformation in the boundary itself, which would also rupture the oxide film, leading to IASCC. Recent work by Alexandreanu (Ref 151) on unirradiated nickel-base alloys has shown that dislocation absorption by the grain boundaries leads to deformation in the grain boundary, usually by boundary sliding, resulting in IGSCC. He investigated grain boundaries classified according to the misorientation of the two grains and was able to determine that the more random the grain boundary, the greater was the sliding under high-temperature deformation. Boundaries on which sliding occurred were four times more susceptible to subsequent IGSCC in primary water at 360 °C (680 °F) than boundaries that did not slide. In this way, he was able to establish a cause-and-effect between grain-boundary deformation and IGSCC. This same process could explain how dislocation injection into grain boundaries by planar slip or dislocation channeling can result in IASCC. In fact, Dropek and Was et al.

Fig. 30 Variation in dislocation channel area, dislocation loop line length, and strain-hardening exponent as a function of dose for neutron-irradiated type 316 stainless steel (SS). Source: Ref 150

(Ref 152) have reported a beneficial effect of grain-boundary engineering on the IASCC behavior of proton-irradiated, controlled purity type 304 alloys after testing in simulated BWR normal water chemistry at 288 °C (550 °F).

The concept that SFE controls the deformation mode, which then increases IASCC, has support from observations of the relative propensity for IASCC of type 304 and 316 stainless steels. Type 316 has, in some cases (Ref 72), been shown to be more resistant to IASCC than is type 304, which may be explained by its higher SFE. Furthermore, observations by Bailat et al. (Ref 153) on neutron-irradiated samples and by Busby et al. (Ref 118) on proton-irradiated

samples both show clear dislocation channel patterns on the surface of type 304 samples that cracked following SSRT, but the absence of those patterns on type 316 samples that did not crack. In addition, SSRT on high-nickel alloys (with SFE around 40 mJ/m²) showed no IG cracking and also no dislocation channeling pattern. Further support for an SFE-based IASCC mechanism comes from the annealing studies cited earlier. On samples that underwent either a short, low-temperature anneal or were tested in the as-irradiated conditions, the IG cracking was accompanied by a high density of dislocation slip bands on the surface of about 65/mm² (42 × 10³/in.²). Annealing at 500 °C (930 °F)

for 45 min resulted in the elimination of IG cracking and also resulted in a reduction in the surface slip band density to ~25/mm² (~16 × 10³/in.²).

The experiments on the nature of deformation described earlier (cold worked versus irradiation) also provide supporting evidence for the effectiveness of dislocation channels in IGSCC. In those experiments, hardening by irradiation was much more effective in initiating IGSCC than was cold work, where the dislocation structure will likely be more cellular than that resulting from deformation of an irradiated condition. As shown along the top of Fig. 26, the slip band density correlates well with the amount of hardening introduced by irradiation and also with the amount of IG cracking, providing a tie-in between deformation mode and IASCC initiation.

A final example of the way in which dislocation channels or slip bands may influence cracking is the observation by Bruemmer et al. (Ref 154) of a correlation between slip band intersection with the walls of a growing crack and the accompanying steps on the oxide on the walls. Figure 31(a) shows a transmission electron micrograph (TEM) of an SCC crack in a cold-worked type 316 stainless steel baffle bolt. Note the slip bands intersecting the walls of the narrow crack at 45° to the crack growth direction. The slip band-crack wall intersections are also coincident with steps in the oxide as shown schematically in Fig. 31(b). This image suggests that the flow of dislocations along the slip steps and into the grain boundary may have been responsible for discontinuous growth of the crack along the grain boundary. While the true role of these slip steps and their angle of intersection with the grain boundary are not yet well understood, these observations provide evidence for a dislocation-based mechanism of cracking in irradiated alloys.

The picture that emerges is one where low SFE and irradiation both lead to planar or localized deformation. Deformation bands terminate at grain boundaries, and, as a consequence, large amounts of displacement in the bands must be accommodated by the boundary. This displacement results in shear strain that can rupture the oxide film at the grain-boundary and cause the initiation of an intergranular crack. For an existing grain-boundary crack, localized deformation will supply dislocations to the crack tip resulting in continual rupture of the crack tip oxide, crack extension, and a higher crack growth rate. As such, localized deformation can lead to both crack initiation and enhanced crack growth.

Radiation Creep and Stress Relaxation

Radiation creep at LWR temperatures results from diffusion of the radiation-produced vacancies and interstitial atoms to dislocations, enhancing the climb-to-glide process controlling time-dependent deformation. Radiation creep can produce both beneficial and detrimental effects. Conceptually, its benefits accrue from a steady relaxation of all constant displacement stresses, for example, weld residual stress and in bolts and in some springs. However, under these conditions—and more so under constant load conditions—radiation creep induces elevated creep rates that may help initiate and sustain SCC. This may result from processes such as grain-boundary sliding, which is believed to be an important reason for the preferential growth of intergranular cracks.

Fig. 31 Transmission electron micrograph of (a) deformation bands intersecting a crack in a baffle bolt (Ref 154) and (b) a schematic of the role that the deformation bands may be playing in IASCC. m, metal; o, oxide; GB, grain boundary

Figures 32 to 34 show the load relaxation that occurs under constant displacement conditions. This process is quite reproducible over a wide range of materials and loading modes and generally produces sizeable (>50%) load relaxation within a few dpa. Thus, for example, in areas of the BWR shroud that receive a moderate neutron flux, if SCC initiation does not occur early in life (e.g., by 1 dpa), the relaxation in residual stress should diminish the likelihood of cracking later in life. Similarly, it is not surprising that the incidence of SCC in BWR shroud beltline welds (exposed to the highest neutron fluence) does not show a strong correlation with fluence.

Radiation creep relaxation also affects PWR baffle bolts, which are subject to large variations in fluence and temperature (Ref 35, 36). This suggests that SCC initiates in baffle bolts either early in life (before significant radiation creep relaxation occurs) or later in life when reloading occurs from differential swelling in the (annealed) baffle plates relative to the (cold worked) baffle bolts.

Creep is also effective in reducing the benefit of compressive residual stress provided, for example, by peening. Figure 35 shows the relax-

ation in surface stress due to neutron or proton irradiation at 288 °C (550 °F) (Ref 159). Between 30 and 60% of the surface residual stress is relaxed by 2 dpa.

Fig. 35 Comparison of neutron-based prediction with proton-induced creep after removing the effect of thermally induced relaxation. Source: Ref 159

While difficult to prove, the elevated and sustained deformation rates associated with radiation creep can accentuate susceptibility to SCC. Estimates of crack tip deformation rates (Ref 1) indicate that radiation creep is not a large contributor in actively growing cracks, but rather it is expected to promote crack initiation and to sustain crack growth (or promote crack reinitiation, if an existing crack does arrest). One mechanism by which creep can affect crack growth is through its effect on dislocation absorption at grain boundaries, resulting in grain-boundary sliding (Ref 151) as discussed earlier.

It is obviously very important to factor radiation creep relaxation into initial component design and subsequent SCC analysis. Its impact is large and occurs (unsurprisingly) in the same fluence range as RIS and radiation hardening.

Mitigation Strategies

Peter L. Andresen, General Electric
Global Research

Gary S. Was, University of Michigan

There are a variety of approaches for mitigating SCC in LWRs, and they are discussed in categories of water chemistry, operating guidelines, new alloys, and design issues and stress mitigation. Since most components in LWRs are not intended to be replaced (and are therefore very expensive to replace), water chemistry is the most attractive mitigation strategy, with operating guidelines and perhaps stress mitigation providing more limited opportunities. While the focus of this article is on IASCC, the primary (especially water chemistry) approaches to SCC mitigation are applicable to both irradiated and unirradiated components.

Water Chemistry Mitigation—BWRs

Because H_2 partitions to the steam phase in BWRs and only about 10 to 15% of the core flow becomes steam (the remainder recirculating in an annulus outside of the core), it is not practical to inject sufficient H_2 to fully suppress radiolysis (which requires about 500 ppb, or $5.7 \text{ cm}^3/\text{kg}$), (refer to Fig. 7b). Radiolysis produces substantial concentrations of oxidants, primarily H_2O_2 , which is not volatile. Therefore, maintaining a stoichiometric excess of H_2 is impossible once boiling occurs in-core. This produces an elevated corrosion potential on the surfaces of all structural materials, increasing their susceptibility to SCC.

Control of water purity is particularly important in BWRs because the elevated corrosion creates a potential gradient in crevices and cracks that concentrates anionic impurities such

as Cl^- and SO_4^{2-} (Ref 5, 52). Until the late 1980s, many BWRs operated at solution conductivities between 0.3 and $0.8 \mu\text{S}/\text{cm}$, which corresponds to 30 to 90 ppb of (usually acidic) impurities (these were often Cl^- and SO_4^{2-} , which are particularly damaging), that were responsible for extensive cracking. Several plants had severe intrusions of impurities from seawater or release of resins into the reactor water, and experienced severe and immediate SCC. By the early 1990s, the fleet average conductivity had decreased to approximately $0.13 \mu\text{S}/\text{cm}$, and it is currently approximately $0.11 \mu\text{S}/\text{cm}$, with much of the residual conductivity (theoretical purity water is $0.055 \mu\text{S}/\text{cm}$) related to chromate (chromium in the oxide films of structural materials becomes soluble at high potential). A conductivity of $0.10 \mu\text{S}/\text{cm}$ represents only about 6 ppb Cl^- as HCl ($1.7 \times 10^{-7} \text{ N}$), and there is a limited value in striving for theoretical purity water because OH^- is present at $2.3 \times 10^{-6} \text{ N}$ in pure water; both logic and modern data support the idea that when the "foreign" anions concentration is well below a tenth of the OH^- concentration, their role in carrying ionic current and thereby changing crack chemistry diminishes. However, SCC growth rates in autoclave outlet water of $<0.065 \mu\text{S}/\text{cm}$ remain reasonably high at high potential, and crevice chemistry measurements show that a shift from acidic to alkaline crack/crevice chemistry occurs in pure water (Ref 47, 52, 61).

The use of buffering species, such as B/Li, phosphate, ammonia, and so forth, is not effective because of the potent effect of the potential gradient in the crack. Crack growth tests in typical commercial PWR B/Li solutions show that, on changing to high corrosion potential, *very high* growth rates result (Ref 160). "Auto-buffering" techniques have been proposed that rely on a change in oxidation state of the species (Ref 52, 161). For example, as NO_3^- is drawn into the crack (which is always at low corrosion potential), it is reduced to NH_4^+ , which is rejected from the crack, and also provides some pH buffering capacity. However, while no increase in growth rate results from moderate concentrations of NO_3^- (e.g., up to 100 ppb), it does not appear to reduce the growth rate that is observed in high-purity water at high (or low) corrosion potential. While it may help mitigate the deleterious effects of Cl^- and SO_4^{2-} , these species are kept at very low levels in modern BWRs.

Hydrogen water chemistry (HWC) involves injecting H_2 into the feedwater, which mixes with the recirculating water near the top of the annulus. It is successful in reducing the oxidant level primarily by gamma-enhanced recombination in the annulus (versus suppressing radiolysis in the core). Because the gamma flux is critical, plants with a wide annulus (lower gamma flux at the pressure vessel) are less responsive to HWC. Because residence time in the gamma flux is critical, the water most strongly affected is the recirculation water, which is drawn from the bottom of the annulus, near a

(shroud support) ledge that seals the bottom of the jet pumps (note that some BWRs use internal pumps, which avoid external recirculation pumps and piping). The water from the recirculation pump drives the jet pumps (about a 1 to 2 drive-to-suction ratio), the top of which starts in the upper part of the annulus. Thus, two-thirds of the water moves rapidly through most of the annulus region, which reduces the opportunity for gamma recombination. Nonetheless, HWC is used in the majority of worldwide BWRs because it provides significant mitigation in the recirculation piping and varying benefit to the components in the lower part of the BWR (shroud and core support structures, control rod drive housings, etc.). Different H_2 injection rates are used, depending primarily on the plant responsiveness to HWC and their tolerance to increased radiation levels in the steam lines and turbine building. At high H_2 levels, the core becomes reducing and the small amount of radioactive ^{16}N (transmuted from ^{16}O in water) changes from soluble NO_3^- to volatile NO_x or NH_3 , as shown in Fig. 7(b). Its half-life is only 7 s, but its presence can raise the radiation level in the steam path by >7 times (Fig. 7). Both the plant design (location and shielding of steam lines and turbine) and the site-boundary limits affect the ability of a given plant to operate at high H_2 injection.

Electrocatalysis employs platinum-group metals to dramatically enhance the efficacy of H_2 injection in lowering the corrosion potential of structural materials (Ref 41, 43). If H_2 is in stoichiometric excess (for forming H_2O), then all of the oxidants (H_2O_2 and O_2) arriving at the surface are consumed catalytically, and the mixed potential for O_2 reduction and H_2 oxidation falls on the H_2/H_2O line at low potential. While making new components out of alloys, or applying weld overlays or thermal spray coatings containing very low levels of platinum-group metals is feasible, the favored approach to creating electrocatalytic surfaces is to introduce soluble platinum-group compounds into the reactor water, for example, at low temperature (e.g., 120°C , or 250°F) or during operation to simultaneously catalyze all of the wetted surfaces, a process called NobleChem (Ref 40–42). Provided the distribution of the platinum-group metal on a microscopic scale is relatively uniform (i.e., small platinum particles separated by less than tens of micrometers), catalytic surface loading of well below a monolayer is adequate to achieve low corrosion potentials and excellent SCC mitigation. Deposition can occur either by electroless reduction, or by formation (or introduction) of very fine (nm scale) particles, which stick to the oxidized surfaces of structural materials. Stress-corrosion cracking susceptibility in general, and growth rates in particular, are significantly reduced at low corrosion potential. The extent of the decreases varies with many factors, including yield strength (Ref 1, 5, 6, 12, 13, 40–42, 44, 50). To be effective in mitigating crack growth, the Pt-group metals must be present in the crack to a greater

depth than O_2 and H_2O_2 , and this requires periodic reapplication. There is isolated evidence that some highly irradiated stainless steels do not show much benefit of low corrosion potential, although a greater body of evidence that shows a strong benefit persists at high fluence (> 20 dpa). The differences in response may result from grain-boundary silicon segregation (Ref 44, 50).

Zinc Injection (Ref 162, 163) and Insulated Protective Coatings (Ref 164, 165) are other methods that can mitigate SCC in BWRs. Zinc improves SCC initiation and reduces radiation buildup by improving the quality of the oxide film and substituting for ^{60}Co in the film. It appears to be less effective in cracks, especially at high corrosion potential (where cation transport in cracks is resisted by the potential gradient). However, even at low corrosion potential, providing an adequate and continuing supply of zinc to the tip of a long, growing crack may be difficult.

Insulated protective coatings (IPC) depend on forming a dense or slightly porous layer on the surface that has very low electrical conductivity. The most attractive coating is ZrO_2 , which can be deposited by various coating techniques, or formed in situ after creating a metallic zirconium layer on the surface, for example, by wire arc or thermal spray techniques. The IPCs do not rely on H_2 injection or even on the presence of H_2 , but it is very unlikely that any technique can be developed to form effective, durable coatings in situ as is done by NobleChem.

Water Chemistry Mitigation—PWR Primary

Commercial PWR primary water uses a coordinated boron (as H_3BO_3) and lithium (as $LiOH$) chemistry to control reactivity and maintain a near-neutral pH at temperature (typically 6.8 to 7.2 at 300 °C, or 570 °F). The boron level at the beginning of the fuel cycle is typically approximately 1500 ppm (with approximately 2 ppm Li), dropping to 100 to 200 ppm (with approximately 0.5 ppm Li) at the end of cycle. There are some suggestions that the high-temperature pH can be optimized to provide some SCC mitigation, but the evidence is mixed and not well supported by any mechanistic insight. Because PWRs use approximately 30 cm^3/kg (2.7 ppm) H_2 , radiolysis is suppressed and the corrosion potential is maintained at its thermodynamic minimum (which varies with temperature, H_2 fugacity, and pH). However, since the relevant metal-oxide phase boundaries have the same pH dependence, there is little hope that small changes in pH will have any effect on SCC. Similarly, while the corrosion potential varies with temperature, H_2 fugacity, and pH, it is close to constant in crevices and cracks, so there is no consequential potential gradient formed.

Zinc Injection and Optimization of H_2 Fugacity. The two most promising water

chemistry avenues for mitigating SCC in PWR primary water are Zn injection and H_2 fugacity optimization (for nickel-base alloys). As with BWRs, the case for zinc mitigation of SCC initiation is stronger than crack growth, although its benefit continues to be evaluated. Optimization of H_2 fugacity is relevant only to nickel-base alloys and is based on the observation of a peak in susceptibility to initiation and a peak in crack growth rate near the Ni/NiO phase boundary (Ref 166–168). Because of differences in the temperature dependence on the H_2/H_2O and Ni/NiO boundaries, the corrosion potential (H_2 fugacity) necessary to stay at (or some fixed distance from) the Ni/NiO boundary varies with temperature. Additionally, the fugacity coefficient decreases markedly above 300 °C (570 °F), so more H_2 is needed at high temperature. The peak in growth rate is approximately three times the “background” rate for lower yield strength materials (e.g., annealed alloy 600), and perhaps seven times higher for high yield strength materials (nickel weld metals, alloy X750, etc.). Trying to stay on the low H_2 side of the peak requires very low H_2 levels at 290 °C (555 °F) (the core inlet temperature), which would create the danger of radiolysis and an elevated corrosion potential. High corrosion potential significantly accelerates crack growth in PWR environments. Current programs are focused on evaluating how effective the high H_2 regime could be in mitigating SCC in nickel-base alloys. Some data show increased IASCC in irradiated stainless steels at high H_2 (Ref 169), but it is unclear whether this is a dynamic straining effect on crack initiation (similar to corrosion fatigue crack initiation) or also an effect on crack initiation at constant load or an effect on crack growth rate.

LWR Operating Guidelines

There are limited ways in which plant operation can be adjusted to minimize SCC. Some operating issues, such as optimizing water chemistry, have already been discussed; note, however, that BWRs vary immensely in their practice of maintaining H_2 injection during operation, with the best at ~99% and the worst at <40%. The primary focus of this section relates to load perturbations. It is widely understood that dynamic loading has a prominent role, both in sustaining and accelerating SCC. Thus, avoiding load following and minimizing adjustments that might produce thermal and pressure fluctuations will be beneficial. For example, Scott et al. (Ref 36) showed that the incidence of SCC in PWR baffle bolts was strongly influenced by load following practice. A second element is the number of startups and shutdowns that plants experience. At least under dynamic straining conditions (slow strain rate or slow cyclic loading), most structural materials exhibit a peak in crack growth rate in the vicinity of 175 °C (345 °F), and the startup environment is more oxidizing and often off-chemistry. In BWRs, H_2 injection cannot be started until power is gener-

ated (so that there is feedwater flow), and in PWRs, H_2O_2 is injected during cool down. Finally, and potentially very importantly, the dynamic strain associated with pressurization and differential thermal expansion (e.g., in ferrite-containing welds) can be a source of significant dynamic strain that promotes SCC. It may be less important that some growth occurs during the approximately 8 h plant startup transient (when higher growth rates are expected than at 288 °C, or 550 °F), than the fact that the dynamic strains and chemistry conditions would reactivate a crack that became dormant under steady-state operation at 288 °C (550 °F).

Design Issues and Stress Mitigation

There are innumerable design issues related to minimizing the incidence of SCC in components. Obviously, reducing design stresses, mitigating weld residual stresses, eliminating crevices, using resistant materials, avoiding abusive grinding, minimizing neutron dose, and so forth are important. Minimizing or managing thermal gradients is also important. For example, in baffle bolts where significant gamma heating occurs, ensuring good coolant flow into the shank area of the bolt is important. Because above approximately 10 dpa and 300 °C (570 °F), radiation-induced swelling may occur, differential swelling may increase the stress. An example is the use of annealed baffle former plates with cold-worked baffle former bolts; the delayed swelling in the cold-worked bolts makes possible an increase in the loading of the bolts as swelling occurs preferentially in the plates.

Welding always creates vulnerabilities to SCC, and research since the mid-1990s highlights the overlooked importance of weld residual strain, which peaks near the weld fusion line at 15 to 25% equivalent room-temperature strain. This underscores the importance of identifying welding methodologies that minimize both residual strain and residual stress and/or complicate the crack path using an uneven/undulating fusion line during multipass welding.

New Alloys

It is clear that many structural materials used in light water reactors are susceptible to SCC. While improvements such as reduced carbon and added molybdenum (e.g., 316L and 316NG), or stabilizing elements such as titanium or niobium, provide resistance to thermal and weld sensitization, these materials in the unsensitized condition clearly retain significant susceptibility to SCC, especially where weld residual stresses and strains exist. The same broad concerns apply to irradiated conditions, where all variants of commercial stainless steels show marked susceptibility to IASCC. While there remain a few “magic dust” avenues to consider, in general too much time has been expended pursuing

subtle variations of the 13-18Cr-8-12Ni nominal stainless steel composition in the hope of achieving dramatic improvements in SCC resistance.

Several known SCC dependencies provide opportunities for improving materials. In both BWRs and PWRs, there is an important role of *yield strength* on crack growth, as shown in Fig. 24 (Ref 5, 45, 51), and the damaging effect of weld residual strains and surface grinding are strongly related to their enhancement in yield strength. Second, chromium depletion makes the grain boundary a highly preferred crack path in pH-shifted crack chemistry that develops at high corrosion potential; at low potential (BWR or PWR) the effect of chromium depletion is not pronounced (Ref 5, 45, 51, 52, 85, 97, 120, 133). Indeed, the presence of grain-boundary carbides retards IGSCC, even at high corrosion potential provided no grain-boundary chromium depletion exists (Ref 44, 50). Materials that have (or achieve by RIS) high silicon levels have high SCC susceptibility (Fig. 11b).

When there is no significant “chemical” preference for crack advance along the grain boundary, it is likely that the intergranular path is preferred because slip accommodation and creep occurs (somewhat) preferentially in the grain boundary (Ref 45, 51). The greater subtlety of the preference for intergranular cracking can be observed by the tendency of the crack to shift to mixed mode or fully transgranular at high “crack tip strain rate,” whether imposed by SSRT, high stress-intensity factors, or increased cycling (higher ΔK or frequency, or shorter hold times at K_{max}). Factors that appear to retard these grain-boundary deformation processes include grain-boundary carbides, higher alloying content (e.g., 30% Cr in alloy 690, and even the elevated iron in alloy 800), wavy slip, and lower temperature. One large difference between PWR primary conditions and BWR low potential conditions is temperature, as most structural components in the BWR are at 274 °C (525 °F) after the cooler feedwater mixes in (some, like the top guide and upper inside diameter of the core shroud are at 288 °C, or 550 °F), whereas the PWR primary water ranges from 290 °C (555 °F) (core inlet) to 323 °C (613 °F) (core outlet) to 340 °C (645 °F) (pressurizer).

Radiation-induced segregation occurs by vacancy and interstitial mechanisms, and results in chromium depletion and corresponding nickel enrichment, although iron is generally also depleted in stainless steels. Increasing the chromium level to compensate for RIS is confounded by the need to maintain phase stability; if chromium is increased then nickel must also be increased, and RIS tends to be enhanced at elevated nickel concentrations (other austenite stabilizers such as manganese have also been considered). One alloying approach to reducing the effect of RIS that looks promising involves the use of oversized elements such as hafnium, cerium, zirconium, and yttrium.

Concern for the effect of silicon on SCC has increased, with observations in special heats of

stainless steels of high (>1.5%) bulk silicon content of high growth rates and little dependence on corrosion potential or stress-intensity factor as shown in Fig. 11(b) (Ref 45). Since silicon segregates primarily by the interstitial mechanisms, and concentrates by ten times or more at grain boundaries during irradiation even at 1 to 3 dpa, it is appropriate to target new alloys at reasonably low silicon content, for example, <0.1% Si.

Radiation hardening is another major factor in the increased susceptibility to SCC. However, the effect of yield strength on SCC is not linear, and it is unclear that moderate reduction in hardening (e.g., from 900 to 750 MPa, or 130 to 110 ksi) will have a consequential effect—and even more unlikely that alloys can be designed that will not exceed, for example, 400 MPa (58 ksi) in yield strength at high neutron fluence.

Slip localization in the form of dislocation channels is the common mode of plastic deformation for irradiated stainless steels in the 300 °C (570 °F) temperature range. The role of localized deformation in IGSCC and IASCC is not well understood; however, there are parallels between IGSCC and slip planarity in the case of unirradiated materials and between dislocation channeling and IASCC in irradiated alloys. The feature common to high susceptibility for both forms of SCC is localized, planar deformation. These observations suggest that factors that homogenize slip (alloying, second phases, etc.) may also mitigate IGSCC and IASCC.

Finally, altering the character of grain boundaries has proved to be an effective mitigation tool in alloy 600. By applying a processing treatment consisting of deformation followed by annealing at a homologous temperature of about 0.7 T_m , random high angle grain boundaries can be transformed into a network consisting of a high density of low angle and special boundaries. Special boundaries are those that have Σ numbers below 29, where Σ is the reciprocal of the fraction of overlapping lattice sites where the two grains intersect. Preliminary data (Ref 103) show that model type 304 and 316 stainless steel alloys containing a high fraction of special boundaries result in less severe cracking compared to the solution-annealed condition, in which random high-angle boundaries dominate.

Irradiation Effects on Corrosion of Zirconium Alloys

Jeremy Busby, University of Michigan

Zirconium alloys are extensively used in the nuclear industry as nuclear fuel cladding and structural fuel assembly components because

they combine a very low neutron absorption cross section with good resistance to high-temperature corrosion and adequate mechanical properties (Ref 170). Nevertheless, uniform waterside corrosion is one of the principal in-reactor degradation mechanisms of zirconium alloys in PWR environments, with localized (nodular) corrosion being of larger concern in BWRs. The intense radiation environment within the reactor core accelerates the degradation of these components, by increasing the rates of corrosion and hydriding, thereby limiting the useful lifetime of the cladding. The integrity of the fuel assembly depends primarily on the performance of the fuel cladding, and its failure is deleterious to the safe and economical operation of nuclear power plants. Therefore, there is great economic incentive to minimize the amount of corrosion that these materials experience in service. The ability of Zircaloy and other zirconium alloys to withstand corrosion and in-reactor degradation is determined by temperature, water chemistry chemical composition, and microstructure (especially the intermetallic precipitates). The key precipitate parameters affecting corrosion are size, morphology, composition, and distribution. Thus the corrosion and hydrogen pickup rates vary not only with alloy composition, but also with the thermo-mechanical treatment (and resulting microstructure).

Economics have driven the operation of nuclear power plants to more severe duty cycles, including higher coolant temperatures, higher discharge burnups, longer fuel cycles, and longer in-core residence times (Ref 171). In response, fuel vendors have introduced alternate zirconium-base alloys and optimized processing. During the 1990s, small changes in Zircaloy-4 alloy chemistry (nominal composition Zr-1.4Sn-0.2Fe-0.1Cr), such as reduced tin content, have improved in-reactor corrosion performance. For more significant improvements the industry has been replacing the Zircaloy-4 fuel cladding in PWRs with more advanced alloys such as Zirlo (Zr-1.0Nb-1.0Sn-0.1Fe) (Ref 172), achieving significant improvements in performance even in the higher duty cycles. Achieving burnups in excess of 70 GWd/MTU will require further improvements in the corrosion performance of zirconium-base alloys and may require further alloy/processing development.

In the general case, the corrosion kinetics (as reflected by weight gain) usually follow parabolic or cubic behavior (t^n where $n = 1/2$ or $1/3$) until the oxide reaches a thickness of 2 to 3 μm , at which point the oxide undergoes a *transition* to linear kinetics ($n = \sim 1$). A closer look at the posttransition regime reveals that corrosion still follows a parabolic or cubic relation, however over a much shorter period, which repeats itself throughout the subsequent oxidation process. The pretransition kinetics can be described by the equation, $w(t) = At^n$, where $w(t)$ is the weight gain, t is the exposure time, and A and n are constants.

Irradiation has a considerable influence on the alloy and oxide layer. Irradiation frequently increases the oxidation rate, although the exact mechanism for this increase is not known. In PWR environments, the corrosion rate increases when the oxide thickness exceeds about 5 μm . Under irradiation, the transition to linear kinetics occurs later than that observed in nonirradiated alloys. Neutron or ion irradiation can influence the corrosion behavior of Zircaloy fuel cladding materials by modifying the water chemistry through the creation of free radicals, which are highly mobile and highly reactive. Irradiation can also impact the properties of the growing oxide layer, most notably by increasing diffusion through the oxide layer, which will enhance the corrosion rate. Irradiation can further influence the underlying metal matrix by creating defects in the crystal lattice, causing RIS near the metal/oxide interface, or perhaps most importantly, causing changes in the precipitate structure. Corrosion of Zircaloy is also affected by the water chemistry and cladding temperature, which change when boiling occurs—this begins about 25% of the way along the fuel cladding in a BWR (very limited boiling occurs in the upper part of the core in some PWRs).

The impact of irradiation on diffusion in/through the oxide layer could play a vital role in the corrosion kinetics. Under irradiation, vacancies and interstitials are created in numbers far exceeding thermal equilibrium values. This excess of vacancies and interstitials promotes diffusion processes and thereby corrosion by increasing the transport of oxygen from the water side of the oxide to the oxide/metal interface.

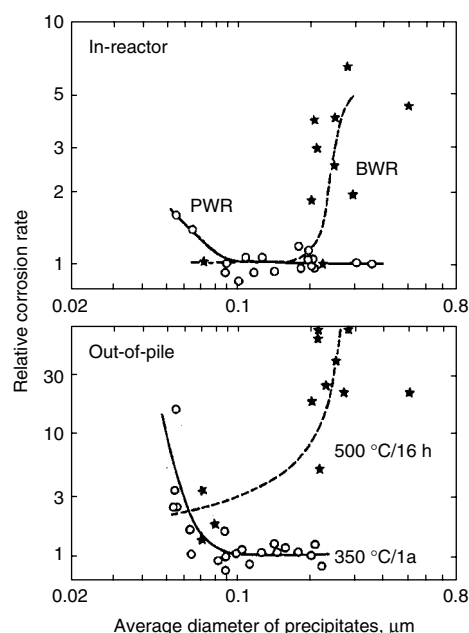

Fig. 36 Relative corrosion rates for cladding with different precipitate sizes in boiling water reactor (BWR)- and pressurized water reactor (PWR)-type environments, when tested in and out of pile. Source: Ref 173

The influence of irradiation on the microstructure of the alloy is one key to understanding corrosion. There is a great deal of empirical knowledge correlating such microstructural parameters as precipitate size, morphology, and distribution (or the annealing parameter) to corrosion performance, hydrogen pickup, and in-reactor performance. The annealing parameter, A , is a simple, single parameter used to describe the combined, accumulated time and temperature of heat treatments. The annealing parameter for any given heat treatment step is usually given as $A = t \exp(-40,000/T)$, where t is the time in hours and T is the temperature in Kelvin. The annealing parameters are then summed for all treatments to gain the cumulative annealing parameter for an alloy (Ref 173). Figure 36 shows the striking correlation of precipitate size with corrosion rate in PWRs and BWRs reported by Garzarolli and Stehle (Ref 173), which is consistent with other studies (Ref 174, 175). In PWRs, large precipitates are desirable to decrease uniform corrosion rates while in BWRs, small precipitates are needed to decrease localized or nodular corrosion. In Zircalloys, these precipitates are typically intermetallics formed when iron and chromium precipitate out of solid solution in the form of Zr(Fe,Cr)_2 .

In the absence of irradiation, during corrosion of Zircaloy, the zirconia layer closest to the metal/oxide interface forms initially in the tetragonal crystal structure. This dense phase at the metal/oxide interface provides the passive/protective layer during corrosion by slowing the transport of oxygen to the metal/oxide interface. However, it is important to note that the tetragonal phase is not the most stable phase at

the temperatures typical of LWR environments. Eventually, as the oxide layer grows thicker, tetragonal zirconia begins to transform into the more stable, monoclinic phase. This phase is not as dense and allows more rapid diffusion of oxygen through the oxide. The transition from tetragonal to monoclinic has been the focus of several recent studies. Yilmazbayhan et al. (Ref 176) measured the fraction of tetragonal phase zirconia using synchrotron radiation. As shown in Fig. 37, the amount of tetragonal phase drops considerably after only a few micrometers of thickness as measured from the oxide/metal interface.

In the initial stages of the oxidation process, the zirconium metal is oxidized preferentially over the precipitates (Ref 177), causing the precipitates to be buried in the oxide layer early in the oxidation process. This is shown schematically in Fig. 38. The precipitates may not begin to oxidize until the surrounding metal phase has been transformed to oxide. During the initial stages of oxidation of a precipitate, the zirconium is oxidized preferentially, releasing chromium and iron to the zirconia matrix (Ref 178). The delayed oxidation of the precipitate is important in the oxidation of Zircaloy as a whole and alters the corrosion process in two ways. First, when the intermetallic undergoes oxidation, the metallic hexagonal close-packed (hcp) phase transforms to the tetragonal oxide, causing an increase in volume. This increase in turn, induces a compressive stress on the oxide layer, which can stabilize the protective tetragonal oxide layer at the metal/oxide interface (Ref 179). The release of chromium and, more significantly, iron, from the second-phase particles, is also important to the uniform corrosion of

Fig. 37 Tetragonal fraction in oxide formed in Zircaloy-4 tested in pure water, calculated from synchrotron radiation micro-x-ray diffraction, versus distance from the oxide/metal interface. Source: Ref 176

Zircaloy. When released from the precipitates, both chromium and iron will also oxidize (which would also act to slow down the transport of oxygen to the interface). The presence of iron in the form of Fe_3O_4 has been shown to stabilize the tetragonal phase and Fe_3O_4 has been observed in the zirconia matrix. So, the release of iron into the middle of the oxide layer helps create a thicker layer of the protective tetragonal phase, thus reducing corrosion rates.

Under irradiation, the precipitates are affected primarily through amorphization (Ref 180). This process is highly dependent on irradiating particle type, irradiation temperature, and dose rate. The interplay of these variables is shown in Fig. 39 (taken from Ref 180), where the dose required to amorphize precipitates is plotted as a function of irradiation temperature and particle type. Further, postirradiation examination

Fig. 38 The role of precipitates in oxidation of Zircaloy-4

reveals that the precipitates are amorphized from the outside to the inside. That is, the outer shell of the particle is amorphous and depleted in iron while the inner core is of the same structure and composition as that prior to irradiation. An example of this phenomenon is shown in Fig. 40 (taken from Ref 181), which shows a TEM image of a $\text{Zr}(\text{Cr},\text{Fe})_2$ precipitate after irradiation with 2 MeV protons at 310 °C (590 °F) to 5 dpa. The energy dispersive spectroscopy (EDS) plot (Fig. 40b) shows that the iron content drops at the edges of the precipitate and rises sharply in the adjacent matrix. The surrounding matrix contains higher levels of chromium and iron, indicating the particles are amorphizing under irradiation.

Since the amorphization of the second-phase particles is not an instantaneous effect, the early stages of corrosion proceed much as they would in the unirradiated case as the precipitates are initially of the same size and composition. However, even as the particles are incorporated into the oxide, irradiation will continue to redistribute iron from the precipitates to the surrounding oxide. Radiation-enhanced diffu-

sion will cause the iron to migrate farther before forming Fe_3O_4 . Thus, each precipitate can stabilize the tetragonal phase in a larger volume of oxide matrix. This would provide a more stable and thicker protective layer, consistent with the slight delay in transition observed in LWR conditions. However, this protective oxide remains intact only until it reaches a thickness of approximately 5 μm , at which point, transition occurs and corrosion continues at an accelerated rate, as mentioned previously.

At longer exposures and higher doses, the precipitates entering the oxide at the metal/oxide interface become smaller due to irradiation-induced amorphization. This has several distinct effects on the uniform corrosion rate. First, the smaller particles tend to result in an oxide with smaller, more equiaxed grains, increasing the corrosion rate as discussed previously. Further, since depletion of iron from the precipitates occurs before entering the oxide, there is no supply of iron to contribute to stabilize the tetragonal phase. All these factors combined result in an accelerated corrosion rate in the post-transition regime.

Considerable progress has been made in improving the corrosion behavior of fuel-cladding materials over the last decade (Ref 182). Several new alloys such as Zirlo (Zr-1.0Nb-1.0Sn-0.1Fe), M5 (Zr-1Nb-O), and NDA (Zr-0.1Nb-1.0Sn-0.27Fe-0.16Cr) have been developed to improve the corrosion resistance of Zircaloy. Other solute additions, such as copper, may also improve corrosion resistance. These advanced zirconium-base fuel claddings are currently being tested in reactor. However, a considerable amount of work remains to be done to fully understand the mechanisms of zirconium-base alloy corrosion and develop alloys that are resistant to both irradiation and corrosion in the higher-temperature regimes of advanced reactor designs.

Corrosion of Zirconium Alloy Components in Light Water Reactors

Clément Lemaignan, CEA France

MOST OF THE POWER REACTORS currently in operation are using natural (light) water as the coolant and moderator and are referred to as light water reactors (LWRs). Higher neutron efficiency may be obtained with heavy water (D_2O) as a substitute for the natural water. However, for all these types of reactors the fuel elements have basically the same design: long tubes filled with fuel oxide pellets—natural or enriched uranium dioxide (UO_2), or a mixed oxide, called MOX, $(U,Pu)O_2$. The tubes may vary in size and geometry. They are all stacked in assemblies for easy handling. For good neutron efficiency the fuel cladding tubes are made of zirconium (Zr) alloys. Typical geometries and operating conditions of the various assembly designs are given in Table 1.

In addition to the cladding, which is a critical component as it acts as the first containment wall for the radioactive fission products, other structural components are made of zirconium-base alloys. Among them, one should consider: the skeleton of the assemblies (the guide tubes—also called thimble tubes—and the spacer grids) and the channel box (in boiling water reactors, or BWRs) or pressure tubes (in CANDU and RBMK as described in Table 1).

All these components are in contact with the primary coolant, whose typical temperatures and pressures are given in Table 1. For all these industrial power plants, the temperatures range between 250 and 310 °C (480 and 590 °F), while

high pressure (7 MPa, or 1 ksi, in boiling reactors to 15 MPa, or 2.2 ksi, in pressurized ones) is applied to obtain a high density of the steam or to maintain water in the liquid phase.

This type of environment is highly aggressive for most of the alloys. Claddings and structural components of the early days of the nuclear industry were made of stainless steels. However, the aim of reducing the ^{235}U enrichment by improving the neutron efficiency, and thus the economy of this source of energy, was a strong driving force for the selection of less-neutron-absorbing materials. Zirconium has been chosen as the base component for the development of alloys to be used in power water reactors. Various types of alloys have been studied, and two major families remain: the Zircalloys, that is, Zr-Sn-O (+Fe, Cr, Ni) alloys, and the Zr-Nb-O alloys (with 1 and 2.5 wt% Nb). Advanced ternary and quaternary alloys are currently under development for higher-performance industrial alloys.

Zirconium Alloys

Zirconium, as a metal, is highly reactive with oxygen and this oxide is very stable (much like Al_2O_3 or UO_2). Thus, the extractive metallurgy of zirconium is complex and requires specific procedures (reduction of zirconium tetrachloride, $ZrCl_4$, by liquid magnesium, vacuum

arc melting, etc.). In addition, hafnium (Hf), a metal with chemical properties very close to those of zirconium (column IV B of the periodic table of the elements), has to be removed completely from zirconium, since hafnium absorbs neutrons. The corresponding purification process is performed early during the processing, by distillation of molten chlorides (Ref 1).

Pure zirconium exhibits two crystallographic structures, depending on temperature. Below 865 °C (1590 °F), the α structure is hexagonal close-packed (hcp), while above this transition temperature β zirconium is body-centered cubic (bcc). The melting temperature of pure zirconium is close to 1855 °C (3370 °F), classifying it as a refractory metal. In the β phase, all the chemical additions to be discussed later are fully soluble. In the α phase there is only limited solid solution of oxygen, tin, and niobium. The transition metals (iron, chromium, and nickel) are almost nonsoluble in the α phase and form intermetallic precipitates, whose size distribution significantly impacts the corrosion behavior, as is described later in this article. Typical compositions of the zirconium alloys are given in Table 2.

The major alloying elements have the following effects: tin (1.2 to 1.7%) improves the mechanical properties, mainly the creep resistance; niobium (1 or 2.5%) is very effective for corrosion resistance; oxygen (around 1250 ppm) is added voluntarily as a hardening

Table 1 Characteristics of water reactor fuel assemblies

Reactor type	Fuel rod							Assembly	Geometry	No. of rods	Coolant			
	Outside diameter		Thickness		Length		Alloy				Temperature		Pressure	
	mm	in.	mm	in.	m	ft					°C	°F	MPa	ksi
Pressurized water reactor (PWR)	9.5–10.5	0.374–0.413	0.6–0.7	0.024–0.028	3.7–4.3	12.1–14.1	Zry4 (Zircaloy4) Zr-1%Nb (M5 [®])	Square	240–300	290–335	555–635	15.5	2.25	
Boiling water reactor (BWR)	12–13	0.472–0.512	0.8	0.031	3.5–4	11.5–13.1	Zry2	Square with channels	55–65	275–285	525–545	7	1.02	
CANDU (CANadian Deuterium Uranium)	13.8	0.543	0.41	0.016	0.5	1.6	Zry4	Cylinder in pressure tube	37	Heavy water 265–310	510–590	10	1.45	
WWER (Russian design PWR)	9.1	0.358	0.7	0.028	3.5	11.5	Zr-1%Nb (E110)	Hexagonal	331	290–320	555–610	15.7	2.28	
RBMK (graphite-moderated Russian design BWR)	13.6	0.535	0.825	0.032	2–3.5	6.6–11.5	Zr-1%Nb (E110)	Cylinder in pressure tube	2–18	270–284	520–545	6.7	0.97	

agent for all the alloys. Transition metals are added to the Zircaloy alloys at low concentrations (below 0.5%). They have been observed to significantly improve the corrosion behavior of the zirconium-tin alloys.

The final heat treatment, after the last cold-rolling pass of the cladding tubes, may be performed within two temperature ranges, corresponding to two types of microstructure:

- The stress-relieved state (SR) is mostly used in PWRs for Zircaloy 4 (Zry4). It corresponds to a final heat treatment at 475 °C (885 °F) for 2 h under vacuum or protective atmosphere, during which the dislocation density is reduced, and without recrystallization of the alloy. The grain shapes remain elongated and highly deformed.
- The recrystallized state (RX) is obtained at higher final heat treatment temperatures of 550 to 600 °C (1020 to 1110 °F). The grains are then equiaxed, with an average grain size in the range of 5 to 7 µm. Due to a much lower dislocation density, the yield strength is reduced, offset by a higher resistance to creep deformation. Zry2 is used in the RX state for BWRs and CANDUs. For the zirconium-niobium alloys, the RX state is generally used. For pressure tubes, specific heat treatments after the extrusion process have been developed. For these alloys, the second-phase particles are niobium-rich bcc precipitates in a Zr (+Nb) matrix.

As zirconium has an hcp structure at temperatures typically used for deformation processing (cold rolling of plates and tubes), the anisotropic deformation mechanisms (dislocation glide on prismatic planes of the hcp crystals and twinning) lead to the development of a strong crystallographic texture of the final products. This texture affects significantly the physical and mechanical behavior (anisotropy in thermal expansion, in mechanical properties, etc.). It does not impact the corrosion itself, but is involved in one by-product of the corrosion: The hydrogen pickup during corrosion leads to the precipitation of brittle hydrides upon cooling, the platelet orientations of which are controlled by this texture.

Corrosion of Zirconium Alloys in Water without Irradiation

As for most of the metallic alloys, the behavior of zirconium in contact with high-temperature water leads to an oxidation reaction, with formation of a solid oxide and release of hydrogen according to:

This leads to the buildup of an oxide layer at the surface of the alloy. The growth of the oxide layer has been shown to occur by diffusion of O^{2-} ions through the oxide and formation of new oxide layer at the metal/oxide interface.

Therefore, this layer acts as a barrier for the development of corrosion. As this layer thickens, the corrosion rate decreases. This protective behavior of the zirconia layer is, however, limited by a transition occurring at a thickness of a few micrometers. The detailed mechanisms of this transformation are still under discussion, but seem to be connected to a phase transformation of the zirconia (ZrO_2) (Ref 2).

Indeed, the crystallographic form of the zirconia at standard temperature and pressure is the monoclinic structure. At high pressure, either the cubic or the tetragonal phase is observed, depending on temperature. During the buildup of the oxide layer, the volume expansion due to the oxide formation at the metal/oxide interface induces compressive stresses in the growing oxide layer to compensate for the local swelling (ZrO_2 has a Pilling-Bedworth factor of 1.56). As the oxide layer grows, these compressive stresses enhance the stability of the tetragonal phase. Due to internal mechanical equilibrium, the compressive stresses cannot increase without limits. For a thickness in the range of 2 to 3 µm, a relaxation process occurs, allowing the zirconia to transform to the monoclinic structure. In an ionic binding material, such as zirconia, this process induces internal cracking. Other phenomena, such as chemical instability of

the tetragonal zirconia in contact with high-temperature water, may contribute to the mechanisms of the crystallographic phase change involved in the transition and to the related development of a porous external zirconia layer (Ref 3).

After this transition, the oxide consists of an internal layer, rich in the tetragonal phase and considered to be dense and protective, above which the outer layer is mostly monoclinic and porous. This structure is transferred continuously as the oxide grows, allowing a constant oxidation rate. As a whole, the corrosion kinetics are described in Fig. 1. A pretransition regime, with a parabolic-cubic behavior controlled by the diffusion of oxygen through the entire protective oxide layer, followed by a more linear regime. The later-stage kinetics are controlled by the diffusion of the oxidizing species through the internal oxide layer, the thickness of which could be considered constant after a few damped oscillations. In the case of zirconium-niobium alloys, the transition is much less pronounced and the evolution of the oxidation kinetics with oxide thickness appears to be better described by an interface rate-controlling step. The dissociation of the water molecule at the oxide/coolant interface has indeed been shown to be a rate-controlling step in this type of alloy (Ref 5).

Table 2 Nominal compositions of zirconium alloys used in LWR reactors

Designation		Nominal composition, wt%					
Grade	UNS No.	Sn	Fe	Cr	Ni	Nb	O
Zircaloy 2	R60802	1.2–1.7	0.07–0.2	0.05–0.15	0.03–0.08	...	(a)

Fig. 1 General oxidation kinetics of Zircaloy in high-temperature water (1 µm ZrO_2 ~15 mg/dm²). Source Ref 4

Various corrosion kinetics laws have been developed to predict the oxide thickness with time. Detailed modeling procedures separate the pretransition and posttransition phases; the pretransition regime is of the type $\varepsilon_1 = \varepsilon_{1,0} \cdot t^{1/3} \cdot \exp(\Delta H_1/RT)$, and the posttransition regime following the equation $\varepsilon_2 = \varepsilon_{2,0} \cdot t \cdot \exp(\Delta H_2/RT)$. In these equations, ε_i is the oxide thickness for the i th regime, $\varepsilon_{i,0}$ is an experimental kinetics constant, t is the time, ΔH_i the activation energies of the oxidation process, R is gas constant, and T is absolute temperature. From a practical viewpoint, the pretransition kinetics and thickness can be neglected for oxide thickness typical of claddings after a few years in reactor (larger than 10 μm) (Ref 6).

Typical values of the parameters used in this equation remain within the following ranges: $\varepsilon_{2,0} = 0.5$ to 2×10^8 $\mu\text{m}/\text{day}$, and $\Delta H_2 = 110$ to 120 kJ/mol. For the current operating conditions of the power reactors, a growth of the oxide layer of 5 to 20 $\mu\text{m}/\text{yr}$ is observed for standard Zircaloy and much less for the more recent zirconium alloys. The activation energy for corrosion is similar to that for the diffusion of oxygen in zirconia, giving credit to the mechanism of oxide growth by diffusion of O^{2-} ions through the oxide layer. For typical LWR temperature conditions, and due to the high activation energy of the corrosion mechanism, an increase in temperature of 20 K will induce an almost two-fold increase in the corrosion rate. Therefore, accurate thermal modeling of the oxide layer is mandatory for a reliable oxidation prediction.

Heat Flow Conditions

During reactor operation, the heat flow through the cladding induces a thermal gradient and the temperature is radial position dependent. Since only the inner part of the oxide is dense and protective, the temperature at this location, that is, at the oxide/metal interface, controls the kinetics of oxide growth. Thus, under conditions of heat flow, such as for fuel cladding, this temperature has to be determined accurately. Usually the coolant temperature and heat flow are well known, and the thermal conductivity of the zirconia is the main parameter controlling the temperature at the metal/oxide interface. The data on the thermal conductivity of such a thin oxide layer, whose structures are complex and may be rather different according to specific corrosion histories, are reported within the range of 1.6 to 2 W/m·K. As the oxide thickens, the thermal barrier due to the oxide layer induces a rise of the temperature at the metal/oxide interface and the corrosion rate increases accordingly. For a typical mean linear heat generation rate of 20 kW/m and an oxide thickness of 40 μm , the oxide/metal interface temperature is higher than the coolant by 20 K, and the corrosion rate increases by a very significant factor of two. In addition to the barrier layer corresponding to the oxide, cruds may be formed during reactor operation and add an additional

temperature increase or may change the local chemical conditions, affecting the corrosion rates (Ref 7).

Detailed computations of the metal/oxide interface temperature require accurate thermal-hydraulics and heat transfer modeling codes. Such approaches should consider the bulk coolant temperature, single- and two-phase flow behavior (pressurized and boiling reactors), limited temperature drop in the loose crud layer (frequent in boiling conditions), and the heat transfer in the zirconia. Several thermal-hydraulic codes have been developed for such computations, and their detailed descriptions are beyond the range of this review on corrosion. Typical profiles are illustrated in Fig. 2.

Impact of Metallurgical Parameters on Oxidation Resistance

The Zircalloys have been developed as variants of binary zirconium-tin alloys. Tin has been shown to reduce the detrimental effect of nitrogen contaminations and was added at concentrations of 1.5 to 1.7 wt%. An uncontrolled contamination of a batch of zirconium-tin alloy by a coupon of austenitic stainless steel has been the fortuitous origin of the development of the Zircaloy series. Out of them only the Zry2 and Zry4 variants remain in current use. As described previously, the solubility of the transition metals (Fe, Cr, Ni) is very low in the hcp α -Zr matrix (typically maximum total solubility of 200 ppm for the sum of them), and all these alloying elements form precipitates of $\text{Zr}_2(\text{Fe,Ni})$ or $\text{Zr}(\text{Fe,Cr})_2$ types. It is therefore not unexpected that the corrosion improvement induced by these transition metals will be strongly dependent of the microstructure of these precipitates (Ref 8).

For pressurized water conditions, large precipitates (larger than 150 nm) are required for the good corrosion resistance, while small ones are preferred for boiling conditions (smaller than 80 nm). The size control of these precipitates is obtained by the successive heat treatments occurring during processing. During the heat treatments in the β -bcc phase, all the alloying elements dissolve and form a solid solution in this high-temperature phase. During quenching, the precipitation of the intermetallics occur, with spatial and size distribution dependent on the cooling rates. The low solubility of these species in the α phase leads to slow coarsening kinetics, and the precipitate sizes remain small unless specific attention is taken in the thermomechanical treatments occurring during tube processing.

In order to control the adjustment of the precipitate sizes of the final products, a cumulative annealing parameter (termed as ΣA or A) is used (Ref 9). It combines all the heat treatments after quenching and is evaluated by:

$$A = \Sigma(A_i) = \Sigma(t_i \cdot \exp(-Q/RT_i)) \quad (\text{Eq } 2)$$

where t_i and T_i are the durations and temperatures of each heat treatment following the β -quench,

and Q is defined by the activation temperature, usually taken as $Q/R = 40,000$ K.

Typical values of the A parameter are in the range of 1 to $5 \times 10^{-17} \text{ h}^{-1}$ for PWRs and 0.1 to $1 \times 10^{-18} \text{ h}^{-1}$ for BWRs, corresponding, respectively, to 200 to 500 nm and 50 to 80 nm for precipitate diameters. An increase in precipitate volume fraction is beneficial for the corrosion resistance (Ref 10). However, the different stoichiometries of the chromium- and nickel-bearing precipitates induce a different effect for increased additions of those elements.

For the zirconium-niobium alloys, the monotectoid transformation at 888 K is to be avoided during heat treatments, as higher temperatures would allow β -Zr precipitates to appear. In order to maintain the microstructure as closely as possible to the equilibrium diagram, heat treatments are therefore performed below this transition temperature, usually at 850 K. The best corrosion resistance is obtained for a microstructure close to the chemical equilibrium. This is indeed obtained with such a thermal history. In addition, during operation in reactors, the irradiation-enhanced diffusion processes allow a further evolution in that direction, improving the corrosion resistance as irradiation proceeds (Ref 11).

For all the alloys, various improvements can be achieved with very specific control of specific minor elements, for example, silicon increased to 150 ppm, carbon limited to 100 ppm, and so forth (Ref 12). Similarly, surface finish also has an impact on the corrosion rates. For instance, it is observed that local impacts or scratches may act as nucleation sites for nodule formation. The usual final surface treatments are either pickling in a nitric acid-hydrofluoric acid bath or finishing (grinding or polishing) with silicon carbide abrasives.

Hydrogen Pickup and Hydriding

The major part of the atomic hydrogen released in the pores of the granular oxide, by the reduction of the water molecules, recombine and form H_2 molecules, remaining in solution in the

Fig. 2 Temperature profile through the oxide layer in heat flow condition. Temperature decreasing from zirconium alloy to coolant

primary water. However, the metallic zirconium alloys may trap a small part of it. Indeed hydrogen may react with zirconium to form a solid solution at high temperature and will precipitate as zirconium hydrides ($\text{ZrH}_{1.6}$) when the temperature is reduced (Ref 13). The diffusion of hydrogen in the zirconia layer is very low ($D_{\text{H-Zr}} < 10^{-15} \text{ m}^2/\text{s}$ at reactor temperatures) and hydrogen ingress cannot occur by bulk diffusion in the oxide layer. Hydrogen uses diffusion short circuits through the metallic precipitates that remain unoxidized in the dense oxide layer. Therefore, they can directly connect the coolant located in the porous oxide to the metallic zirconium alloys.

The fraction of hydrogen trapped in the alloy (pickup fraction) depends on the alloy (composition and microstructure) and also on the oxidation conditions (temperature and water chemistry). Typical values are around 0.15 to 0.25 for Zry4 in PWRs, 0.3 to 0.6 for Zry2 in BWRs, and approximately 0.1 for 1% Nb alloys. The higher value of the hydrogen pickup for Zry2 has been explained by the presence of nickel in this alloy, a noble metal enhancing catalytic reactions with hydrogen. Once trapped in the alloy, the hydrogen cannot escape and its concentration increases with time. It can reach a few hundred ppm at the end of life of the component (Ref 14).

The solubility of hydrogen in zirconium alloys is strongly temperature dependent, with a heat of solution of 64 kJ/mol. At 320 °C (610 °F) the solubility of hydrogen is approximately 90 to 110 ppm, while at room temperature it is below 1 ppm. Thus, after irradiation, the oxidized cladding exhibits precipitation of zirconium hydrides as platelets. The morphology of the hydride platelets is controlled by the cooling rate (hydrogen diffusion kinetics), by the stress state (hydrides expand at formation), and by the crystallographic texture (habit planes of the hydrides close to basal plane of zirconium). These hydrides are brittle at low temperature and the precipitation of hydride platelets during cooling, if their orientations favor a cracking path through them, reduces the ductility of the alloy in case of low-temperature stress or impacts. This could occur during fuel handling in pool and transport. At operating temperatures, the hydrides are ductile and do not affect the mechanical properties of the zirconium alloy components (Ref 15).

Oxide Morphology and Integrity

The oxide layers grown in reactor may exhibit various morphologies:

- In reducing water environments, such as in PWRs, the first oxide layers, before the transition, are black (hypostoichiometric) and of uniform thickness. After the transition, lighter oxides can be observed, with small local variations in thickness. After the transition, layers of internal cracks or porous zones, parallel to the interface, have been reported.

They have limited spatial extensions, are separated 3 to 5 μm apart, and may play a role for the spalling of the oxide layer described below (Ref 2).

- In less reducing environments (BWR type), the oxide layers may not be as uniform. At early stages of oxidation, local oxide growth instabilities occur, producing thick oxide spots or nodules. Once nucleated, the nodules grow in diameter and thickness, but their number remains constant. Improvements in alloy compositions and heat treatments reduce the occurrence of this type of corrosion mechanism. Typical aspects of this “nodular” corrosion are given in Fig. 3.

Oxide layers of high thickness have been observed in reactors in several cases of specific conditions, where zirconium alloy components are facing dissimilar metals. This can occur in front of Inconel holding springs or stainless steels parts, for example, control crosses in BWRs. Increases in oxide thickness of five- to tenfold have been reported. Known as “shadow corrosion,” this phenomenon only occurs under irradiation and cannot be duplicated without neutron or gamma flux (Ref 16). Local irradiation enhanced radiolysis has been suggested to explain the phenomenon (Ref 17), but local electrochemical conditions under irradiation are now considered as the critical parameter driving “shadow corrosion” (Ref 18).

For high thickness (above 50 to 100 μm), the oxide layer may locally spall out. Flakes of oxide, a few mm^2 in size, are released in the coolant. The effect of this behavior is twofold: due to the thermal barrier made by the zirconia, the local spalling reduces the oxide thickness and, as a consequence, the temperature at the oxide/metal interface is reduced. The oxidation rate should locally decrease. On the other hand, this local “cold spot” is a location for preferential diffusion of the hydrogen in solution. In the

worst cases, solid hydrides across the cladding thickness may be observed in spall-out areas (Ref 19). The local massive precipitation of hydrides will increase the local oxidation rate, even if the temperature is lower. In addition, it induces locally a strong embrittlement of the cladding, a matter of concern in the case of low-temperature mechanical loads, as described previously.

Effect of Irradiation on Microstructure and Corrosion

The irradiation damage, induced by the fast neutrons knocking the metal atoms and inducing displacement cascades and point defects, leads to changes in microstructure. Among the various changes induced by irradiation, one should consider those that may affect the corrosion behavior:

- In the Zircalloys, the secondary phases (Zr_2Ni and ZrCr_2 types) are ordered phases. During the recombination of vacancies and interstitials, the replacement of a displaced zirconium atom may be realized by an iron, chromium, or a nickel atom and, vice versa, a mechanism that induces a local chemical disorder (antisites). For typical LWR conditions, this is the physical origin of an irradiation-induced crystalline-to-amorphous phase transformation observed within these phases. This occurs especially with the ZrCr_2 -type precipitates and is linked to significant chemical composition changes (iron is released from the precipitate to the matrix). Since the chemistry and sizes of these phases are critical parameters with respect to corrosion behavior, this irradiation-induced microstructure change has been observed to severely affect the corrosion resistance after irradiation (Ref 20).

Fig. 3 Nodular corrosion in Zircaloy 2 fuel cladding. (a) Unaided view. (b) Scanning electron micrograph enlargement.

- For the zirconium-niobium alloys, the niobium solubility decreases with temperature and the zirconium matrix is supersaturated with niobium after the final heat treatment at 550 to 580 °C (1020 to 1075 °F). Due to the irradiation-enhanced diffusion of niobium under irradiation, the time under irradiation leads to the chemical equilibrium with additional niobium precipitation as nanometric bcc niobium precipitates. Thus, for these alloys, the irradiation permits a faster return to the chemical equilibrium at the irradiation temperature, a state of higher corrosion resistance (Ref 21).

As an example of the effect of the irradiation-induced microstructure change on oxidation rate, Fig. 4 describes the corrosion behavior of two coupons of Zircaloy (base metal and weld), tested in an autoclave after irradiation, compared with the same alloy not irradiated. The weld had a very fine microstructure due to the β quenching, and the intermetallics dissolved early during irradiation, obliterating the corrosion resistance. For the base metal, a similar behavior is observed, but less pronounced, as the precipitates were larger at the beginning of the irradiation and were only partly transformed during irradiation.

LWR Coolant Chemistry

Various technical constraints impact the water chemistry. In PWRs, soluble neutron absorber is added as boric acid in solution (H_3BO_3) to control the core reactivity. Its concentration decreases as the cycle proceeds, from about 1600 to 500 ppm, at a rate of approximately 3 ppm/day. To counterbalance the low pH, lithium hydroxide (LiOH) is added as an alkalinizing agent (2.2 to 0.7 ppm). The normal pH at temperature is 6.9 to 7.2, depending on the time during the cycle. Such a high pH is required to avoid corrosion of stainless steel and the transport of activated chemical species from the core to the cold spots, like the steam generator. However, it has been shown that lithium has a detrimental effect on zirconium alloy corrosion that seems to be mitigated by the presence of the boric acid. A tendency exists to reduce the maximum allowable lithium concentration. In WWER (Russian-designed PWR) the alkalinizing agent is often potassium hydroxide (KOH). In the CANDUs, due to continuous reload, no reactivity compensation is needed in the coolant, and the only chemical addition in water is LiOH to increase the pH to 7.6 in operation.

With respect to the effect of radiolysis, H_2 is added in the primary water of single-phase reactors (PWR, WWER, CANDU) (typically $30 \text{ cm}^3 \text{ STP.kg}^{-1}$, i.e. 3.5 ppm). It can be shown that H_2 catalyzes the recombination of the radiolysis species, as well as the initial dissolved oxygen, allowing a low oxidation potential in PWR water. In the case of BWRs, the H_2 separates from the water phase and escapes in the

steam. In these reactors, a high oxidation potential remains in the coolant outside the core and can lead to intergranular cracking occurring on primary piping. Reducing conditions can, however, be obtained by H_2 additions, and now almost all BWRs operate under hydrogen-controlled water chemistry. This is obtained with continuous H_2 injection in the feedwater of the core (Ref 23). The typical coolant conditions of water reactors are given in Table 3.

Corrosion of Fuel Rods in Reactors

As a whole, the corrosion behaviors in reactors will combine all the effects described previously. Figure 5 shows a plot of the oxide thickness of two fuel rods of the same assembly after 4 years of irradiation in a PWR. Several features can be observed. Oxide thickness generally increases along the fuel rod because the coolant temperature increases as it is heated by the fuel. In the lower part of the core, the corrosion rate is low due to a temperature close to the inlet

temperature (see Table 1), while the upper parts of the rods exhibit higher oxide thickness. At a finer scale, large oscillation in oxide thickness can be observed. They correspond to the enhanced heat exchanges induced by the mixing effects of the grids. Downstream of the grids (above them as the coolant flows upward), a more turbulent flow enhances heat exchanges and reduces the temperature of the oxide in contact with the water. Typical distance between grids for PWR and BWR are approximately 0.5 m (1.6 ft). Specific research and development is focused on improving the turbulent efficiency of the grids without increase of the corresponding pressure drops. Finer observation reveals higher-order oscillation related to the fuel pellet/pellet interfaces, where hydride precipitation had occurred, locally increasing the corrosion thickness.

Usually the design rules do not precisely state the maximum oxide thickness allowable during operation. However, other design constraints (remaining cladding mechanical properties, thermal fuel profile, etc.) lead to a maximum oxide thickness of approximately $100 \mu\text{m}$. The

oxide thickness observed for the standard alloys irradiated in reactors operating in demanding conditions have been close to this value. This fact has been a strong driving force for the development of new, more corrosion-resistant alloys, such as the low-Sn Zry4 variants, the Zirlo (1-Sn, 1.03-Nb, 0.01-Fe) (Westinghouse Electric Co.), or the M5 (1-Nb, O) (Areva Framatome ANP).

Corrosion of Containment Materials for Radioactive-Waste Isolation

Raúl B. Rebak and R. Daniel McCright, Lawrence Livermore National Laboratory

RADIOACTIVE MATERIALS are extensively used in a variety of applications such as medical, weapons, and power generation. Once these materials lose their commercial value they are considered radioactive waste. Broadly, the wastes can be separated into defense (weapons) and civilian (power, medical) (Ref 1).

The safe disposal of radioactive waste requires that the waste be isolated from the environment until radioactive decay has reduced its toxicity to innocuous levels for plants, animals, and humans. Many different types of radioactive waste are produced during commercial and defense nuclear fuel cycles. One type of waste, denoted high-level waste (HLW), contains the highest concentration of radiotoxic and heat-generating species. Because of this factor, the most stringent standards for disposing of radioactive wastes are being placed worldwide on HLW, and the majority of the radioactive-waste management effort is being directed toward the HLW problem. One of the most common types of HLW is the spent nuclear fuel (SNF) from commercial nuclear reactors for power generation.

All of the countries currently studying the options for disposing of HLW have selected deep geologic formations to be the primary barrier for accomplishing this isolation. It is postulated that by the own nature of these geological sites, they will contain the waste for long times, avoiding its spread, for example, through water flow. Most of the repository designs also plan to delay the release of radionuclides to the environment by the construction of engineered barrier systems (EBS) between the waste and the geologic formation. The principal engineered component in this multibarrier approach is called the waste package and includes the waste itself, possibly a stabilizing matrix for the waste (together termed the wasteform), and a metallic container that encloses the wasteform. Beyond the metallic containers, other barriers could be added to attenuate the impact of the emplacement environment on the containers. These barriers include, for example, the drip shield proposed in

the U.S. design or a bentonite backfill proposed in several European designs (Ref 2, 3).

The waste container may be a single vessel, but current designs generally call for concentric double-walled vessels of dissimilar metals. Each vessel will have a specific function. For example, the container that directly holds the wasteform may be designed to shield radiation and facilitate safe waste handling and emplacement operations. This container may be overpacked with a corrosion-resistant outer layer. This article addresses the long-term corrosion behavior of HLW container materials, more specifically of the outer shell of the containers.

Several countries are currently studying the viability of the geologic disposal of nuclear waste. The design of the different containers for nuclear waste would vary according to the nature of the geologic formation at the site of the repository. That is, the materials (metals or alloys) that may be used for the external wall of the container would depend on, for example, whether the redox potential of the surrounding environment is predicted to be mostly reducing or mostly oxidizing and what major corroding species would be present at the site. In 2001, there were more than 30 nations currently considering the geological disposal of HLW (Ref 3). Table 1 shows a list of nations, the intended geologic formation, the type of environment, and the current proposed design for the containers (Ref 2, 3). The material selection and its behavior in each type of emplacement are discussed separately.

Time Considerations

In the last 15 years, the predicted length of time for the safe survival of the HLW repository sites has increased. In 1987, when the previous version of this article was published, most of the repository designs specified from 300 to 1000 years. In 2004, the minimum length of time specified for many repositories has increased

to 10,000, 100,000, and even to 10^6 years (Ref 2, 4–6).

The requirement that a waste container survive intact for thousand of years in an irradiated elevated-temperature geologic environment has created a difficult problem for materials and design engineers to solve. The unique aspect of this problem is associated with making predictions about the corrosion behavior of container materials for these extended periods of time, since many of the alloy systems being considered have been in existence for less than 100 years. The viability of extrapolating corrosion data from short-term testing to long-time performance has been addressed by some investigators (Ref 4, 7, 8). Other researchers proposed models to predict the lifetime performance of container alloys (Ref 9, 10). For example, corrosion-rate values from 5 year tests is expected to be extrapolated to times as long as 10,000 years, that is, more than three orders of magnitude (Ref 11). The problem associated with interpreting results for long-term behavior based on accelerated testing has been addressed by the ASTM Committee C-26 on Nuclear Fuel Cycle, who prepared the standard C 1174 that provides guidelines, among other issues, on the corrosion testing of materials (Ref 12). ASTM C 1174 also recognizes that actual data on the long-term behavior of materials in repositorylike conditions will not be available to be used in the design of the waste package. Therefore, ASTM C 1174 establishes that short-time (10 years) data need to be used to support the development of predictive behavior models for the response of the waste package over times as long as 10,000 years. ASTM C 1174 provides guidelines on how to perform accelerated corrosion tests to compensate for the shorter testing time. These acceleration factors may include the use of more concentrated solutions, higher temperatures, and applied potentials. The accelerating factors described in ASTM C 1174 may be used provided the degradation (alteration) mechanism(s) remains the same. The effects of accelerating conditions should be quantified and

mechanistically described before they are used for lifetime predictions.

Environmental and Materials Considerations

Many of the countries that are considering the emplacement of HLW in geological repositories have recognized the importance of an underground research laboratory (URL) for the characterization of the rock, the testing of materials for environmental degradation, and other studies. The most common host rocks for nuclear waste repositories in the world are clay and granite (Table 1). The containers are intended to be located in alcoves buried vertically down from the ground level, that is, below the water table. The depth of emplacement may vary from country to country, but it is generally assumed to be on the order of 100 to 500 m (330 to 1640 ft). The only nonsaturated (above the water table) environment for a repository is the one projected for the United States. That is, the Yucca Mountain repository will be emplaced in tunnels buried, still underground, but horizontally into a mountain.

According to the value of the redox potential, an environment can be categorized as mostly reducing or mostly oxidizing. In the case of a reducing redox potential, the cathodic reaction is mostly controlled by the hydrogen discharge reaction. An oxidizing redox potential is established by cathodic reactions other than hydrogen reduction, for example by the reduction of dissolved oxygen. Most of the repository environments in the world will be reducing based on redox potentials, due to the fact of depth (where the solubility of oxygen in water is minimal) and a projected backfill with bentonite (Table 1). The intended function of the backfill is to retard the diffusion of oxygen toward the containers.

The repository in the United States will not have restrictions regarding the availability of oxygen to contact the containers; that is, the redox potential will be oxidizing in nature, provided an aqueous solution materializes.

The important environmental parameters affecting corrosion include container temperature, groundwater chemistry (including microbial activity), groundwater flow rate, hydrostatic and lithostatic pressure (which influences water phase and container stress), and radiation flux.

Radiation. Theoretically, radiation can affect the corrosion behavior of the container by affecting both the container environment and its metallurgical properties. The general conclusion reached by most investigators is that the types and dose rates of radiation emitted from decaying wastes are not sufficient to degrade the properties of either the container material or its passivating oxide layer. Only gamma radiation from the HLW can affect the environment, because the other forms of radiation will not penetrate the container walls. It has been suggested that radiation may produce changes in the external environment, for example by controlling microbial activity or radiolysis of ground water. Currently, the United States plans to accept the most active waste for disposal (5 years out of reactor). This waste will produce maximum dose rates at the container surface of 10^3 to 10^5 rads/h.

Water Chemistry. The groundwaters associated with the crystalline-rock formations should all be relatively benign to most materials because of their low ionic strengths, near neutral pH, and low concentrations of halide ions (Table 2) (Ref 6). The corrosivity of these waters could increase if significant groundwater vaporization occurs when high container temperatures exist during the early times following emplacement.

Temperature. The container temperature may be influenced by the design and loading of

the waste package (size, thermal output, radiation output), the rate and density of waste package emplacement, and the thermal properties of the formation. Because heat is a significant by-product of HLW decay, the temperature of all waste containers will initially increase and then decrease as the activity of the waste decays. The predicted temperature history for 3 kW waste packages emplaced in a consolidated volcanic ash (tuff) formation in the United States is not expected to be higher than 160 °C (320 °F) (Ref 6). Typical maximum container temperatures for a number of other repository locations are expected to be lower than 100 °C (212 °F) (Ref 2). The variability in maximum temperature is due primarily to design philosophy. The temperature at a given location can be lowered by longer waste aging before emplacement, lower package loading, and lower overall repository loading. The lower temperatures may enhance the performance of the entire waste package and

decrease the impact of emplacing waste on the geologic formation itself. However, a penalty is incurred for lower temperatures because higher handling and emplacement costs, along with a larger usable area, are required.

Materials. An analysis of Table 1 shows that, except for the United States, most of the materials for the containers will consist of carbon steel, stainless steel, and copper. These metals are not in the high end of the scale of corrosion-resistant alloys. That is, the emphasis of the design is on a controlled environment. Also, the emphasis of the containment of the waste is put on the barriers beyond the outer layer of the metallic container. Contrarily, the materials for the engineered barrier in the U.S. repository are some of the most corrosion-resistant materials available today in the market of industrial alloys. That is, most of the responsibility of containing the waste in the United States is put on the environmental resistance of the alloys of the engineered barriers. The composition of candidate alloys is given in Table 3.

In general, engineers carry out the selection and characterization of the materials for the EBS and project their performance as a function of the emplacement time. However, the fact that one of these repositories is actually going to be built and put in service may depend largely on the public support based on their perception about whether the site would be safe.

Reducing Environments

This section discusses environmental corrosion resistance of materials planned for reducing repositories (Table 1). These containers will generally be surrounded by a backfill of bentonite, which will greatly limit the availability of oxygen to the metal surface. The lack of oxygen (or other oxidizing species) will create a redox potential that will be closer to the hydrogen evolution reaction. Elements such as iron (Fe),

nickel (Ni), and copper (Cu) are mostly in the range of corrosion immunity at these reducing potentials in the near-neutral pH range (Ref 13). The most common materials under study in typically reducing environments are carbon steel, stainless steel, copper, and titanium (Tables 1 and 3). For the least corrosive underground waters, carbon steels could be viable materials; however, for the most saline conditions, titanium alloys are also being studied. For example, the groundwater in the crystalline-rock disposal environment in the Canadian shield was expected to be benign (no halide ion, neutral pH, low ion strength) (Ref 14). During a research drilling program, groundwater containing 5.6 g/L of chloride ion was encountered. The existence of isolated pockets of saline groundwater in the deep rock formations supports the need for careful site characterization studies (Ref 15).

Carbon Steel and Low-Alloy Steel

Carbon and low-alloy steel have been extensively been tested in groundwater environments for the last 30 years. Corrosion rates measured for carbon steels in granite waters ranged from 3 to 55 $\mu\text{m}/\text{yr}$ (0.12 to 2.2 mils/yr), with one study showing that the rate reaches a maximum at around 80 °C (175 °F) (Ref 16). The conditions that would lead to localized corrosion of carbon steels are quite specific and unlikely to be present in typical granitic groundwaters (Ref 17). However, hydrogen embrittlement and hydrogen blistering of low-alloy steels are possible in granitic environments with a high rate of hydrogen production (Ref 17). Carbon steel will also have low corrosion rates in basalt waters (Table 4) (Ref 18). Even in oxygenated solutions at 150 °C (300 °F), the corrosion rate of all tested carbon steels in basalt waters was on the order of 100 $\mu\text{m}/\text{yr}$ (4 mils/yr) (Table 4). In another series of tests, 1020 carbon steel, cast carbon steel, cupronickel 90-10, and

Source: Ref 18

Fe-9Cr-1Mo steel were tested in anoxic (<0.1 mg/L dissolved oxygen) basalt groundwater at 200 °C (390 °F) for 5 months (Ref 19). The corrosion rates were: 0.9 $\mu\text{m}/\text{yr}$ (0.035 mil/yr) for cupronickel 90-10 and Fe-9Cr-1Mo steel, 1.1 $\mu\text{m}/\text{yr}$ (0.043 mil/yr) for cast carbon steel and 1.4 $\mu\text{m}/\text{yr}$ (0.055 mil/yr) for wrought carbon steel. Under the Swedish program, researchers have studied the anoxic corrosion behavior of carbon steel and cast iron in groundwater at 50 and 85 °C (120 and 185 °F), and the impact of the presence of copper on the type and the mechanical properties of the films formed on the iron alloys (Ref 20, 21). They used a barometric cell filled with simulated groundwater and monitored the redox potential in the cell at 30 °C (85 °F) on a gold electrode. They determined that when steel was introduced to the cell, the redox potential decreased rapidly due to the consumption of the residual oxygen by the corrosion of the steel (Ref 20, 21).

As part of the Japanese program of nuclear waste disposal, the localized corrosion behavior of plain carbon steel was studied at 90 °C (195 °F) using the Tsujikawa-Hisamatsu Electrochemical (THE) method (Ref 22). It was reported that the crevice repassivation potential increased as the chloride concentration decreased and the carbonate/bicarbonate amount

increased; that is, carbonate inhibits the crevice corrosion susceptibility of carbon steel (Ref 22). The passive corrosion behavior of steels was found to be dependent on variables such as groundwater pH, temperature, and available dissolved oxygen (Ref 23). Scientists in the Japanese program have raised the concern that whenever the corrosion of steel decreases due to a decrease in the oxygen content, the alkalinity in the immediacy of the steel increases. This may increase the rate of hydrogen gas production that could be detrimental for the stability of the repository (Ref 24). In another study, it has been shown that the corrosion rate of carbon steel is dependent on the amount of bicarbonate (HCO_3^-) present in the water (Ref 25). At bicarbonate levels of 0.1 M, similar to the geological disposal site, the corrosion of carbon steel is inhibited.

Carbon steel has also been identified as candidate material for rock salt repositories in the German program. Studies were conducted to determine the corrosion response of welded and nonwelded Fe-1.5Mn-0.5Si steel in a magnesium chloride (MgCl_2) rich brine (Q-brine) at 150 °C (300 °F) under an irradiation field of 10 gray/hour (Gy/h, one gray equals 100 rads) (Ref 26). Welding was carried out using gas tungsten arc welding (GTAW) and electron beam (EB) welding. The overall corrosion rate of both welded and nonwelded materials was approximately 70 $\mu\text{m}/\text{yr}$ (2.8 mils/yr); however, the welded materials experienced some localized attack in the weld seam area. When the material was heat treated for 2 h at 600 °C (1110 °F), the corrosion rate of the welded material increased by approximately 40% (Ref 26).

Carbon steel and low-alloy steel has also been identified as candidate material to contain nuclear waste for an intermediate storage of 100 years in the French program (Ref 27). The dry oxidation testing of carbon steel in dry air (less than 15 ppm water), in air plus 2% water and in air plus 12% water at 300 °C (570 °F) for up to 700 h showed little damage to the tested coupons. When the depth of the oxide layer was extrapolated to 100 years, it resulted in less than 150 μm (6 mils) of damage. The authors also noted little or nil water vapor effect on the oxidation rate at 300 °C (570 °F) (Ref 27).

Copper

The container for the disposition of nuclear waste in Sweden will consist of a 50 mm (2 in.) thick layer of copper over cast ductile iron, which will provide the mechanical strength. Groundwater in granitic rock (as in the Swedish repository) is oxygen free and reducing below a depth of 200 m (655 ft). The redox potential is between -200 and -300 mV in the hydrogen scale and the pH ranges from 7 to 9 (Ref 5). The chloride concentration in the groundwater can vary from 0.15 mM to 1.5 M with an equivalent amount of sodium and less calcium. The corrosion of a copper container in this reducing

environment is expected to be less than 5 mm (0.2 in.) in 100,000 years of emplacement (Ref 5). The corrosion of copper is mainly controlled by the availability of oxygen, sulfate, and sulfide in the groundwater. The failure time of the copper layer in the Swedish container has been modeled, and it is predicted that the failure, both by general and pitting corrosion, would be greater than 10^6 years under realistic emplacement conditions (Ref 28).

The anodic behavior of copper was also studied as part of the Japanese nuclear waste disposal program using potentiodynamic polarization tests in simulated groundwater at 30 °C (85 °F) (Ref 29). The amount of dissolved oxygen as well as different additions of chloride, sulfate, and bicarbonate was controlled. The researchers concluded that both sulfate and chloride promote the active dissolution of copper while carbonate is a passivating agent (Ref 29).

In the Canadian design, the thickness of the external layer of the copper layer is 25 mm (1 in.). Scientists have modeled the failure mechanism of copper as a function of the oxygen availability, the temperature, the salinity of the solution, and the redox potential. It is predicted that copper will undergo general corrosion and pitting during the initial warm and oxidizing period, but only general corrosion during the subsequent longer anoxic cooler period. It has been predicted by this model that the Canadian copper container could last more than 10^6 years (Ref 30).

The long-term corrosion rates of many copper-base alloys are also sufficiently low, <20 $\mu\text{m}/\text{yr}$ (<0.78 mil/yr) at 200 °C (390 °F), that their use now appears feasible. When a copper container is buried in a mostly reducing environment, the metal will initially be in contact with oxygen, until the oxygen is fully consumed, for example by corrosion (Ref 31–33).

It is known that copper may suffer environmentally assisted cracking (EAC) such as stress-corrosion cracking (SCC) in waters containing, for example, ammonia and nitrite (NO_2^-). It has been shown that copper alloys, candidate materials for the Canadian waste containers, were susceptible to SCC using the slow strain rate technique (Ref 34). It has been reported that the crack growth rate could be as high as 8 nm/s (3×10^{-7} in./s) (Ref 35). However, the conditions under which the damage occurred were extreme and unrepresentative of container emplacement conditions. In the actual container, the general absence of aggressive SCC species, the limited applied strain, and the limited supply of oxygen will limit the susceptibility to environmental cracking. In another study, it has been shown that the minimum stress for crack propagation in copper for the Swedish container was 30 $\text{MPa}\sqrt{\text{m}}$ (27.3 $\text{ksi}\sqrt{\text{in.}}$) when tested in a 0.3 M sodium nitrite (NaNO_2) solution (Ref 36). A stress intensity of 30 $\text{MPa}\sqrt{\text{m}}$ (27.3 $\text{ksi}\sqrt{\text{in.}}$) can be considered high for a statically loaded container having shallow defects on the surface.

Stainless Steel and Nickel Alloys

The cyclic potentiodynamic polarization method (ASTM G 61) was used to evaluate the anodic behavior of corrosion-resistant alloys in oxidized Boom clay water (in Belgium) with varying degrees of added chloride at 90 °C (195 °F) (Ref 37). The original Boom clay water is dominated by chloride and sulfate. The alloys studied included type 316L stainless steel (also with high molybdenum and with titanium) (UNS S31603), alloy 926 (N08926), alloy 904L (N08904), alloy C-4 (N06455), and Ti Gr 7 (R52400) (Table 3). It was found that both R52400 and N06455 resisted pitting corrosion even at added chloride concentrations of 10,000 ppm and N08926 resisted pitting up to 1000 ppm chloride. The other alloys showed minor pitting at 100 ppm chloride and definite pitting corrosion at the higher tested chloride concentrations (Ref 37).

Titanium

Titanium (Ti) alloys are under study as candidate materials for the containers in Canada, Japan, and Germany. The titanium alloys were selected as a potential alternative because of their excellent performance in more aggressive brine solutions compared, for example, to stainless steels. Corrosion rates for Ti Gr 2 and Ti Gr 12 in both oxygenated and irradiated basalt environments are very low—less than 2 $\mu\text{m}/\text{yr}$ (0.08 mil/yr). Failure models for the degradation of Ti Gr 2 have been published (Ref 38). The model takes into account the crevice propagation rate as a function of temperature and oxygen availability as well as other factors such as the amount of hydrogen absorbed by the alloy during corrosion before a critical concentration for failure is reached (Ref 38). The localized corrosion resistance of titanium alloys was widely investigated using the THE method (Ref 39, 40). Testing showed that as the temperature and the chloride concentration increased, the repassivation potential (E_{RCREV}) for Ti Gr 1 and Ti Gr 12 decreased to values well below the corrosion potential (E_{corr}) (Ref 39). Ti Gr 12 was more resistant to crevice corrosion than Ti Gr 1. At constant temperature and chloride concentration, E_{RCREV} increased as the palladium (Pd) content in the alloy increased, rapidly up to 0.008% Pd and then slower between 0.008% to 0.062% Pd (Ref 40). In most of the tested electrolytes, the E_{corr} was lower than E_{RCREV} for the palladium-containing titanium alloys, suggesting that crevice corrosion will not initiate in the titanium-palladium alloys at the free corrosion potential (Ref 40).

Titanium alloys were also investigated for their resistance to EAC. One way by which titanium alloys may suffer EAC under reducing conditions is by the formation of hydrides (Ref 41). Slow strain rate testing was conducted using Ti Gr 1 in deaerated 20% sodium chloride (NaCl) at 90 °C (195 °F) at an applied potential

of -1.2 V (standard hydrogen electrode, SHE) (Ref 42). It was confirmed that cracks initiated as deep as the presence of hydrides, and it was therefore dismissed that the containers may fail by cathodic EAC (Ref 42).

Oxidizing Environments

As mentioned previously, the United States is currently the only country that has designed and is characterizing a nuclear waste repository with an oxidizing environment surrounding the waste package. This repository is planned to be located in Yucca Mountain, Nevada. The design of the waste package has evolved in the last 10 years (Ref 6, 43). Since 1998, the design specifies a double-walled cylindrical container covered by a titanium alloy drip shield. The outer shell of the container will be a Ni-Cr-Mo alloy (N06022) (Table 3) and an inner shell of nuclear-grade austenitic type 316 stainless steel (S31600). The function of the outer barrier is to resist corrosion, and that of the inner barrier is to provide mechanical strength and mainly shield radiation. The drip shield will be made of Ti Gr 7 (Table 3). The function of the drip shield is to deflect rock fall and early water seepage on the container (Ref 6).

Earlier and Current Design of the Yucca Mountain Waste Package

Waste package designs and selection of materials have changed over the years, and the changes have usually occurred in various design phases associated with the preparation of comprehensive project planning documents. Consideration of Yucca Mountain as a potential repository site began in the late 1970s. At that time, the U.S. Department of Energy was also considering other locations with other types of geological formations. In late 1982, the U.S. Congress passed legislation (Nuclear Waste Policy Act) that codified the process for characterizing prospective geological repository sites. Work continued at the Yucca Mountain site (in tuff rock) and also at specific sites in the state of Washington (in basalt), in Texas (in bedded salt), and at a general site to be selected later in an eastern state (presumably in granite). In late 1987, the Nuclear Waste Policy Act was amended, and work at all the sites except Yucca Mountain was terminated. A comprehensive Site Characterization Plan was formulated for the Yucca Mountain site and issued in early 1989.

The very earliest waste package design was common for all of the U.S. repository sites. This was sometimes called the self-shielded container since it was quite thick (about 300 mm, or 12 in.) and made from steel or cast iron. The thick package could readily withstand high stresses or pressures from the outside, plus the bulk of the waste package reduced the radiation level significantly outside the waste package. In late 1982, it was determined that the repository could be constructed in the unsaturated zone, some

300 m (985 ft) above the permanent water table. This differentiated the Yucca Mountain site from those being studied elsewhere. The early design of the waste package specific for the Yucca Mountain site (often called the Site Characterization Plan design) consisted of a single, relatively thin barrier of approximately 20 mm (0.8 in.) thick. Because the waste packages could be emplaced in drifts in the unsaturated zone, relatively thin barriers would provide sufficient strength against external pressures (this is in contrast with the packages proposed for other countries in the saturated zone that must withstand either hydrostatic or lithostatic pressures). Furthermore, the heat produced by the radioactively decaying waste could be used as a thermal barrier, evaporating water in the vicinity of the waste package and keeping water away for hundreds of years while the temperature on the waste package container surface was well above the boiling point of aqueous solutions relevant to the site.

Early work at Yucca Mountain focused on austenitic stainless steels as the container material, particularly on type 304 stainless steel (S30400) (Table 3). At that time, the waste package was being designed for a 300 to 1000 year lifetime with a fairly large number of breached waste packages permitted in the performance assessment of the system. Because the prevailing environmental conditions at the Yucca Mountain site are oxidizing, materials whose corrosion resistance depends on the formation of protective passive films have been viewed as the most viable materials for construction of the waste package. Over the years, the performance demands on the waste package have increased considerably, and this has resulted in the selection of more and more corrosion-resistant materials for the container. In the 1980s, the container materials work was centered on type 304L stainless steel as the "reference material" with other 300-series austenitic stainless steels and related alloys (such as alloy 825—N08825) as alternatives because of improved resistance against localized corrosion or SCC.

During this same period, some work was performed on copper and copper-base alloys as candidate waste package container materials. Although the prevailing conditions at Yucca Mountain are expected to be oxidizing, some of the copper-bearing alloys, such as aluminum bronze (C61300), copper-nickel (C71500), and nickel-copper alloy 400 (N04400) do perform reasonably well under such conditions. Some of the copper-bearing materials continue in test today as possible alternative materials to those in the present design. These materials generally have corrosion resistance intermediate between corrosion allowance materials, such as carbon steel, and corrosion-resistant materials, such as nickel-base and titanium alloys.

In 1991, the Yucca Mountain Project (YMP) entered into another design phase that included a more robust waste package. The robust feature of the waste package design was achieved in three

ways: (a) use of a double container consisting of a corrosion-resistant material for the inner container and a corrosion-allowance material for the outer container, (b) a thicker waste package, and (c) a highly corrosion-resistant material for the inner barrier. The outer barrier would be made of carbon steel, while the inner barrier would be made of a nickel-base alloy. The outer barrier would be about 100 mm (4 in.) in thickness, while the inner barrier would be around 20 mm (0.8 in.) thick. The strategy was that the carbon steel would corrode very slowly in the initially hot and dry atmosphere and then more rapidly as the temperature cooled and aqueous conditions could develop in the repository. It was initially proposed to make the inner container out of alloy 825 (N08825), but because of the need to demonstrate higher corrosion resistance, alloy 625 (N06625) was chosen, only to be finally replaced by alloy 22 (N06022). It was further proposed that the two containers be shrink-fitted together so that a partially corroded steel outer barrier would provide cathodic protection to the inner nickel alloy inner barrier. A further option was added to the design: a thermal sprayed ceramic coating over the carbon steel surface. This design phase ended in 1998 with the issuance of the Viability Assessment Report.

The waste package design was further modified in 1998 for the next phase. The corrosion-resistant barrier became the outer container (alloy 22). The inner container would be fabricated from a nuclear grade of type 316L stainless steel, twice as thick as the external layer. The function of this inner container is to provide added strength and bulk to the waste package. These two container shells will be manufactured separately and assembled as a slip fit with the stainless steel inside the alloy 22 (Ref 6). In addition, a drip shield, made from titanium, will be installed above the waste packages to divert any water seeping and rock falling from the drift wall, away from the waste package. The specific grade of titanium recommended for this design phase was Ti Gr 7 (R52400), containing palladium to provide extremely high corrosion resistance. The strategy of this design was that the highly corrosion-resistant Ti Gr 7 and alloy 22 would provide greater defense in depth since they would be highly unlikely to suffer from the same type of failure. The waste package and drip shield combination is needed to endure for some 10,000 years, with very few breached containers allowed in this time period, in order to achieve a very high standard of protection to the accessible environment around Yucca Mountain. This design remains the current design and was used for the Site Selection phase, which ended in 2002, when Yucca Mountain was selected by the President and approved by the Congress to go forward with a License Application to the U.S. Nuclear Regulatory Commission (NRC). This same design will be used in the License Application process. Since the actual construction of waste packages is still years away, additional testing of alloy 22 is continuing. Also, other Ni-Cr-Mo alloys are currently in test as

alternatives to alloy 22. Work is also proceeding on alternative materials to the expensive Ti Gr 7 drip shield, including thermal sprayed ceramics and metal glasses on various substrates.

Effects of Fabrication on Corrosion Behavior. In parallel with the work on investigating the corrosion behavior of the various materials under repository-relevant environmental conditions, efforts have evolved on evaluating processes to fabricate and weld the waste package containers. The corrosion behavior of a material is often related to the metallurgical condition of the material resulting from the processes used in fabrication and welding. In the design proposed for the License Application, the container body will be fabricated from rolled and welded plate. The specified welding process is GTAW with matching filler material (Ref 6). Assembly welds, that is, the welds used to join the pieces of rolled plate together as well as the weld to join the bottom lid to the container shell, will be annealed and quenched. The empty container shells (inner stainless steel and outer alloy 22) will then be filled with the waste, and then the top lids will be welded on. Because of the high radioactivity of the filled waste package, the final closure weld must be made in a hot cell, so that much of the operation will be performed robotically. The GTAW process will be used to make the two closure welds. The annealing and quenching operation on the outer alloy 22 container shell puts the surface in compression. After the top alloy 22 lid is welded onto the now-filled container, the welded area will undergo a stress-relief operation to put down a compressive stress layer. Processes for achieving this include laser shock peening and metal burnishing, both of which can be conducted in a hot cell operation. The strategy is to prevent any possibility of initiating SCC by eliminating sources of tensile stress. Since the first waste package will not be fabricated for several more years, it is expected that changes in the processes described will be made to improve the projected performance of the container material and to ensure a very high degree of quality control. The emplacement of the first waste package at the Yucca Mountain site is planned for 2010.

Carbon and Low-Alloy Steel

Carbon steel was an earlier candidate for the container material in the United States. This is no longer the case; however, the characterization of the corrosion behavior of carbon steels in Yucca Mountain type environments is still important since other components (e.g., rock bolts, tunnel ribs, borehole liners, etc.) in the drifts may still be constructed using carbon steels. Table 5 shows corrosion rates of carbon steels, low-alloy steels, and stainless steels at 100 °C (212 °F) in both steam and water (Ref 44). Table 5 shows that in general all tested materials had lower corrosion rates in steam than in water, especially for the longer testing times. Table 5 also shows that the corrosion rate of stainless steels is almost

negligible, even for those with only 13% Cr such as type 416 stainless steel (Table 3). The effect of irradiation on the corrosion rate was also studied (Ref 44). A gamma dose of 3×10^5 rads/h was applied for 3 months in the presence of only J-13 water and in presence of tuff rock plus J-13 water, both at 105 °C (220 °F). J-13 is the name of a well in the Yucca Mountain area from where the groundwater was analyzed. The corrosion rate of carbon steel and alloy steel was higher in the presence of irradiation and also, under irradiated conditions, the corrosion rate was higher when the rock was present in the environment. It was explained that the production of oxygen and hydrogen peroxide may have increased the corrosion rate of the tested materials (Ref 44). Corrosion rates by weight loss were measured for carbon steel, cast iron, and alloy steel in air saturated J-13 water in the temperature range 50 to 100 °C (120 to 212 °F) for 1500 h (Ref 44). Results show that for all the alloys a maximum corrosion rate was reached in the 70 to 80 °C (160 to 175 °F) range and decreased at 100 °C (212 °F). This could be related to the amount of dissolved oxygen in the tested electrolyte. At 100 °C (212 °F), the corrosion rate of 1020 carbon steel, gray cast iron, and 2.25Cr-1Mo alloy steel was approximately 300 µm/yr (11.8 mils/yr); however, for 9Cr-1Mo alloy steel the corrosion rate was only 7 µm/yr (0.28 mil/yr) (Ref 44). Carbon steel 1020 was also investigated regarding the effect of water vapor or relative humidity (RH) on its corrosion behavior at 65 °C (150 °F) (Ref 45). It was determined that a RH between 75 and 85% is necessary before 1020 carbon steel suffered any obvious corrosion damage (Ref 45). The effect of relative humidity on the corrosion susceptibility of carbon steel has also been modeled (Ref 46).

The corrosion rate of 1016 carbon steel was measured in concentrated J-13 type of water (Table 2) using electrochemical techniques (Ref 47). The corrosion rate was always below

10 µm/yr (0.40 mil/yr) for all the tested waters at 25, 50, 70, and 90 °C (75, 120, 160, and 195 °F). Only in dilute aerated water (10 times the concentration of J-13) was the corrosion rate of the carbon steel higher than 10 µm/yr (0.40 mil/yr). A comprehensive review of the corrosion modes of carbon steels regarding nuclear waste disposal evaluated the different degradation modes such as microbiologically influenced corrosion (MIC), general corrosion, localized corrosion, and EAC (Ref 48). The corrosion behavior of A516 carbon steel was studied at 25, 65, and 95 °C (75, 150, and 205 °F) in solutions containing different levels of carbonate/bicarbonate and chloride (Ref 49). It was found that one of the most important parameters controlling the mode and rate of corrosion were pH and the ratio of chloride to total carbonate.

Stainless Steels and Nickel Alloys

The evaluation of the corrosion resistance of type 304L stainless steel and alloy 825 was conducted via electrochemical testing such as the cyclic potentiodynamic polarization (CPP or ASTM G 61) (Ref 50). The testing matrix included 33 different environmental variables including radiation effect. The electrolyte solutions were concentrated versions of J-13 well water (Tuff rock in Table 2). Results showed that both 304L and alloy 825 experienced pitting corrosion under the tested conditions. As expected, alloy 825 was more resistant to localized attack than 304L. Detrimental variables that were identified included chloride and hydrogen peroxide. Beneficial variables included bicarbonate and nitrate (Ref 50). Cyclic potentiodynamic polarization tests were also used to compare the localized corrosion behavior of several resistant alloys, from carbon steel A516 to corrosion-resistant nickel- and titanium-base alloys (Ref 51). The tests were carried out in

Table 5 General corrosion rates of candidate steels in 100 °C (212 °F) tuff-conditioned saturated steam and water

Test duration: ~30 weeks

Material	Corrosion rate in J-13 Water at 100 °C (212 °F)		Corrosion rate in J-13 Steam at 100 °C (212 °F)

up to 4 wt% ferric chloride (FeCl_3) solution, pH 1.6 at 30, 60, and 90 °C (85, 140, and 195 °F). As expected, the degree of attack increased with the salt concentration and test temperature. Results show that the ranking of the alloys regarding their resistance to corrosion was as follows: K01800 < N08825 ~ N06985 < N06625 < N06030 ~ N06455 < N06022 < R53400. Alloy 22 (N06022) suffered only minor crevice corrosion and Ti Gr 12 (R53400) did not suffer any visible attack. In the creviced areas of tested specimens of alloy 625 and 22, a high concentration of molybdenum oxide was found. It was also reported that, at 90 °C (195 °F), the E_{corr} of Ti Gr 12 was approximately +600 mV (in the saturated silver-silver chloride scale or SSC) and that of A516 carbon steel was approximately -400 mV (SSC), and it did not depend on the concentration of FeCl_3 between 1 and 4% (Ref 51). This large difference in the E_{corr} of Ti Gr 12 and A516 could result in galvanic corrosion of A516 if these two metals are put in contact in the studied corroding solution.

Near Field Environment at the Repository

The groundwaters that are associated with Yucca Mountain have been well characterized (Ref 52). In particular, most emphasis has been placed on the composition of water from the J-13 well as being representative of water that would originate from atmospheric precipitation and would infiltrate along fractures in the various tuff layers including the Topopah Spring layer in which the repository would be constructed. Other types of waters, including simple salt solutions, such as concentrated calcium chloride (CaCl_2) brines, have also been considered during the testing of waste package (container and drip shield) materials. One such type of water is pore water that would be formed in an upper rock stratum and then find its way also along the fractures leading into the repository drifts. Many of the salts associated with the Yucca Mountain waters are hygroscopic in nature. Over the emplacement years, the temperature decreases and the relative humidity increases in the atmosphere around the container. Eventually a point is reached where an aqueous solution can be maintained because of the deliquescence point of the salt mixture that may be deposited as dust on the surface of the container. Solutions with relatively high concentrations of salts in the water are therefore the most representative of aqueous environmental conditions. Nevertheless, the climate at Yucca Mountain is dry and water quantities reaching the waste package surface are favorably limited. The performance of the material under aqueous conditions may be poorer than those under dry conditions. The dry oxidation rate of alloy 22 at the temperatures of operation is negligible. The enrichment of dilute groundwaters will follow the chemical divide; that is, the nature and amount of each species that could be present in the final drop of water will

depend on the relative amount of species in the originating water. Two commonly mentioned waters that may be present at Yucca Mountain are:

- The infiltration water is a bicarbonate-dominated type of water with significant concentrations of sulfate, nitrate, and chloride. Alkali (Na and K) cations dominate over alkaline earth (Ca and Mg). The water also contains some fluoride and is saturated in silica. Its pH is just slightly alkaline in the dilute water, but with concentration of its salts, the pH is raised into the 10 to 11 range, mainly because of the bicarbonate/carbonate buffering effect.
- The pore water is characterized by the absence of any carbonate species. It contains significant amounts of sulfate, nitrate, and chloride, but the alkaline earth cations dominate over the alkali cations. It is slightly acidic when diluted but when concentrated, it remains near neutral, since there is no carbonate to alkalize the solution.

In both cases, a high concentration of nitrate develops, owing to the high solubility of nitrates. Evaporative concentrations of groundwater lead to high nitrate concentrations. This is significant with respect to corrosion performance because the nitrate is an important factor in establishing the overall redox conditions. Nitrate ion also demonstrates inhibiting effects in localized corrosion initiation and probably stress corrosion; thus mitigating the effects of aggressive ions, such as chloride and fluoride. Other oxyanions in solution such as sulfate, carbonate, and silicate also seem to show mitigating or inhibiting effects on localized corrosion.

The peak surface temperature that develops on the waste package container surface depends strongly on how closely the waste packages are placed in the repository drift. Historically, the strategy of the repository design configuration was to elevate the waste package container surface above the boiling point to keep the surface dry and defer any aqueous corrosion effects. In the present design, a maximum peak surface temperature of approximately 160 °C (320 °F) will occur on the waste packages once the repository is closed. The temperature decays slowly, requiring hundreds of years until temperatures below the boiling range are attained. However, more recently the project has also considered and studied an option for keeping the peak surface temperatures at a much lower value (-85 °C, or 185 °F) by using a less compact arrangement of the waste packages in the repository. However, this option means that aqueous corrosion conditions will be encountered at a much earlier time after waste emplacement and puts additional emphasis on the performance of the waste package materials.

Microbial Activity. There is abundance of microbiological life in the repository setting. Microbial activity is expected once sufficient moisture is present (e.g., >90% RH). However, the main concern is their effect on changes in the

water chemistry. For instance, types of microbes (bacteria and fungi) producing acids, microbes oxidizing iron (steel is used in the repository construction), and microbes producing strongly reducing conditions (sulfate reducers) could lead to scenarios that might be damaging to alloy 22 and titanium. However, current studies have not found consistent evidence that microbial activity is actually damaging to alloy 22 or Ti Gr 7.

Radiolysis. One further environmental effect is the influence of radiolysis on changes in the water chemistry. The relatively thick two-barrier design attenuates the gamma radiation field by approximately 3 orders of magnitude. The major gamma-producing isotopes have half-lives around 30 years; thus each 100 years in the repository reduces the radiation field by another order of magnitude. The main concern with radiolysis is the combination of a significant gamma field with aqueous conditions, which may produce damaging species such as hydrogen peroxide. This is certainly more of an issue if a lower thermal load of waste packages is used in the repository when water may be present while the waste will be highly radioactive.

Corrosion Behavior of Alloy 22 (N06022)

By designation, the Ni-Cr-Mo alloy 22 (N06022) listed in Table 3 is the corrosion-resistant barrier of the waste containers for the Yucca Mountain Project (Ref 6). When evaluating the corrosion resistance of the container, no credit is given for corrosion resistance to the internal thicker layer of type 316 stainless steel nuclear grade. The container may suffer corrosion if water is present in sufficient amount at the repository site. Dry corrosion of alloy 22 is negligible for the emplacement conditions. There are three main modes of corrosion that the container may suffer during its lifetime of 10,000 or more years. These are: (a) uniform or passive corrosion, (b) localized corrosion (e.g., crevice corrosion), and (c) EAC (e.g., SCC). All types of corrosion will be influenced by the metallurgical condition of the alloy and the type of environment that is present. Metallurgical condition includes, for example, welded versus wrought and annealed versus thermally aged microstructures. The environmental aspect includes temperature, solution composition and pH, redox potential, and effect of radiation or microbial activity. Furthermore, both the metallurgical and environmental conditions will determine the free corrosion potential (E_{corr}) of the container. Since 1998, alloy 22 is being intensively characterized regarding its corrosion resistance in a variety of environmental conditions. The sections that follow describe the results by type of failure mode.

Uniform and Passive Corrosion of Alloy 22. General corrosion (or passive corrosion) is the uniform thinning of a metal (container) at its E_{corr} (Fig. 1). In the presence of aerated multiionic brines, alloy 22 is expected to remain

passive at its E_{corr} . The degradation model for the designed container assumes that general corrosion at E_{corr} will progress uniformly over a large surface at a (time-independent) constant rate. This model assumes that the depth of penetration or thinning (x in μm) of the container is equal to the corrosion rate (CR, e.g., in $\mu\text{m}/\text{yr}$) multiplied by the time (t in years) that the container is exposed to an environment under which general corrosion occurs. For example, if the corrosion rate for alloy 22 is $0.1 \mu\text{m}/\text{yr}$ ($0.004 \text{ mil}/\text{yr}$), the uniform thinning of the container in 10,000 years will be $x = 1 \text{ mm}$ (0.04 in.). General corrosion

rates are currently being measured using long-term weight-loss immersion tests and shorter-term electrochemical methods in a variety of environmental conditions. Table 6 shows values of corrosion rates measured under several testing conditions using different testing methods.

After a 2 year immersion of alloy 22 coupons in concentrated aqueous electrolytes from pH 2.8 to 10 in the temperature range between 60 and 90°C (140 and 195°F), the average corrosion rate determined by mass loss was approximately $0.02 \mu\text{m}/\text{yr}$ ($0.0008 \text{ mil}/\text{yr}$) (Ref 53) (Table 6). Electrochemical impedance studies of mill

annealed (MA) and aged alloy 22 at E_{corr} in J-13 water at 95°C (205°F) showed that after immersion times of less than 3 h in normally aerated solutions, the corrosion rate was approximately $0.2 \mu\text{m}/\text{yr}$ ($0.008 \text{ mil}/\text{yr}$) (Table 6) (Ref 54). The corrosion rate did not depend on the thermal aging conditions of the tested specimens. Constant potential tests on alloy 22 immersed in deaerated 0.028 M and 0.5 M NaCl solutions of pH 2.7 and 8 were performed at 20 and 95°C (70 and 205°F) (Ref 60). After holding the potential constant for 48 h in the range between 0 and $+0.4 \text{ V}$ (saturated calomel electrode, SCE), Dunn and Brossia reported (Ref 60) passive currents that translated into corrosion rates of less than $0.5 \mu\text{m}/\text{yr}$ ($0.02 \text{ mil}/\text{yr}$). Constant potential tests were also performed on alloy 22 in deaerated 1 M NaCl + 0.1 M sulfuric acid (H_2SO_4) solution at temperatures between 25 and 85°C (75 and 185°F) (Ref 55). At 75°C (165°F) and at an applied potential of $+200 \text{ mV}$ using a silver/silver chloride ($\text{Ag}/0.1 \text{ M AgCl}$) reference electrode, Lloyd et al. reported a current density of $1.58 \times 10^{-8} \text{ A}/\text{cm}^2$ after 10 h of testing (Ref 55). This current density translates into a corrosion rate of $0.138 \mu\text{m}/\text{yr}$ ($0.005 \text{ mil}/\text{yr}$) (Table 6). Polarization resistance tests were carried out in the vicinity of the E_{corr} of alloy 22 in simulated acidified water (SAW) (Ref 56). The SAW is a multicomponent aqueous solution approximately 1000 times more concentrated than J-13 (Table 2) and acidified to pH near 2.8. After an immersion of 1 h in deaerated conditions, the corrosion rates ranged from $0.480 \mu\text{m}/\text{yr}$ at 30°C ($0.019 \text{ mil}/\text{yr}$ at 85°F) to $1.440 \mu\text{m}/\text{yr}$ at 90°C ($0.057 \text{ mil}/\text{yr}$ at 195°F). However, after 1 week immersion in aerated SAW, the corrosion rate decreased by more than one order of magnitude to $0.023 \mu\text{m}/\text{yr}$ at 30°C ($0.0009 \text{ mil}/\text{yr}$ at 85°F) and to $0.103 \mu\text{m}/\text{yr}$ at 90°C ($0.004 \text{ mil}/\text{yr}$ at 195°F) (Table 6) (Ref 56). Constant potential tests were performed in aerated and deaerated SAW and simulated concentrated water (SCW) at 90°C (195°F) and at potential values of $+0.1 \text{ V}$ and $+0.4 \text{ V}$ (Ag/AgCl) (Ref 57). The SCW has a pH of approximately 8 to 10 and is 1000 times more concentrated than J-13. After 1 day testing in deaerated solutions at $+0.1 \text{ V}$, it was reported that the corrosion rates were $0.460 \mu\text{m}/\text{yr}$ ($0.018 \text{ mil}/\text{yr}$) in SAW and $1.250 \mu\text{m}/\text{yr}$ ($0.049 \text{ mil}/\text{yr}$) in SCW. After the 1 day current density decay is extrapolated to 1 year, the corrosion rates became $0.021 \mu\text{m}/\text{yr}$ ($0.0008 \text{ mil}/\text{yr}$) and $0.100 \mu\text{m}/\text{yr}$ ($0.004 \text{ mil}/\text{yr}$), respectively (Ref 57).

It is difficult to obtain corrosion rates by weight loss of alloy 22 in nonaggressive solutions such as simulated concentrated groundwater, since the mass losses are practically negligible. The corrosion rate for alloy 22 was in general less than $0.01 \mu\text{m}/\text{yr}$ ($0.0004 \text{ mil}/\text{yr}$) after more than 5 years immersion tests in multiionic solutions (Ref 58, 59). These corrosion rates were obtained after analyzing 122 specimens exposed at two temperatures (60 and 90°C , or 140 and 195°F), using two

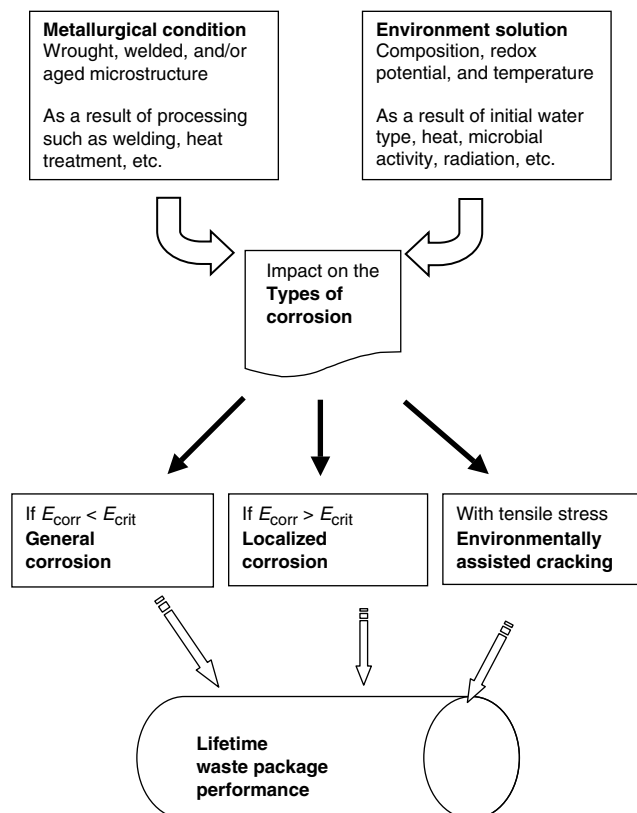

Fig. 1 General model for corrosion degradation of alloy 22

metallurgical conditions (wrought and welded), three electrolyte solutions (pH 2.8 to 10), and vapor plus liquid phases (Table 7) (Ref 58, 59). Figure 2 shows that the corrosion rate of alloy 22 was practically the same in all the tested conditions in the Long Term Corrosion Test Facility (LTCTF) at Lawrence Livermore National Laboratory (LLNL). Moreover, since the corrosion rate was low and the temperature span of testing was not large, a clear relationship between corrosion rates and temperature could not be obtained. In another immersion test experiment, welded and nonwelded alloy 22 coupons were exposed to basic saturated water (BSW) solution at 105 °C (220 °F) for up to 8 weeks (Ref 61). The reported corrosion rates were on the order of 0.25 to 0.76 $\mu\text{m}/\text{yr}$ (0.01 to 0.03 mil/yr) both for welded and nonwelded materials. It was argued that since the mass loss for alloy 22 was the same for the 4 weeks and the 8 weeks exposures, the corrosion rate of alloy 22 would decrease as the testing time is increased (Ref 61).

The low corrosion rates or passive behavior of alloy 22 is believed to be caused by the formation of a protective, chromium-rich oxide film between the alloy (metal) and the surrounding electrolyte. It has been shown that the thickness of this passive film could be only in the range of 5 to 6 nm (Ref 62). The long-term extrapolation of the corrosion rate of alloy 22 has been modeled considering that the dissolution rate is controlled by the injection of oxygen vacancies at the oxide-film/solution interface (Ref 63). It has been concluded that according to the

modeling it is unlikely that catastrophic failure of the container may occur due to long-term passive film dissolution (Ref 63).

The available data in the literature reported previously shows that the general corrosion rate of alloy 22 in acidic to alkaline solutions is expected to be well below 0.100 $\mu\text{m}/\text{yr}$ (0.004 mil/yr). Therefore, it is concluded that failure of the containers in Yucca Mountain will not occur by passive dissolution.

Localized Corrosion of Alloy 22. Localized corrosion (crevice corrosion) is a type of corrosion in which the attack progresses at discrete sites or in a nonuniform manner. The degradation model (Fig. 1) assumes that localized corrosion will only occur when E_{corr} is equal or greater than a critical potential (E_{crit}) for localized corrosion. That is, if $E_{\text{corr}} < E_{\text{crit}}$, only general or passive corrosion will occur. The E_{crit} can be defined as a certain potential above which the current density or corrosion rate of alloy 22 increases significantly and irreversibly above the general corrosion rate of the passive metal. In environments that promote localized corrosion, E_{crit} is the lowest potential that would trigger localized (e.g., crevice) corrosion. In environments that are benign toward localized corrosion such as the simulated concentrated groundwaters in Table 2, E_{crit} is of no significance. In these environments, under sufficient polarization, the current density on a metal may increase due to transpassive behavior of the elements in the alloy or to oxygen evolution by the decomposition of water. The margin of safety against localized corrosion will be given by the value of $\Delta E = E_{\text{crit}} - E_{\text{corr}}$. The higher the value of ΔE , the larger the margin of safety for localized corrosion. It is important to note here that the values of both E_{corr} and E_{crit} depend on the surface condition of alloy 22, the composition of the environment (e.g., chloride concentration), and the temperature. Additionally, the value of E_{crit} may depend on the way (method) it is measured. Researchers commonly use CPP (ASTM G 61) or the THE method (Ref 64) to determine localized corrosion (mostly crevice) repassivation potentials

(Ref 65–68). This crevice repassivation potential is generally equated to E_{crit} . In many instances, since the true value of E_{crit} is not known, researchers use values of potential in cyclic polarization curves at which the current density on a test specimen reaches a given value of current density (e.g., the potential to reach 20 $\mu\text{A}/\text{cm}^2$ in the forward denoted as E_{20} or the potential to reach 1 $\mu\text{A}/\text{cm}^2$ in the reverse scan denoted as $ER1$) (Ref 56, 60, 68–70). These latter values of potential are for comparative purposes only and may not imply the occurrence of localized corrosion.

Alloy 22 is extremely resistant to localized corrosion such as pitting corrosion and crevice corrosion. Critical temperatures for pitting and crevice corrosion determined through immersion tests in aggressive solutions are always among the highest for nickel alloys (Ref 71, 72). Electrochemical tests also confirmed the resistance of alloy 22 to crevice corrosion. The repassivation potential for crevice corrosion (E_{crit}) of alloy 22 was approximately 300 mV (SCE) in 1 M NaCl at 95 °C (205 °F) (Ref 73–75). Cyclic potentiodynamic polarization tests using seven types of Ni-Cr-Mo alloys showed that the repassivation potential for MA alloy 22 in 1 M NaCl solution at 50 °C (120 °F) was above 400 mV (SCE) (Ref 71). Similar CPP tests in 5 M CaCl_2 pH 6.4 solutions showed that the passivity breakdown potential was higher than 800 mV (saturated silver chloride, SSC) at 75 °C (165 °F) and decreased to 195 mV (SSC) at 90 °C (195 °F) (Ref 56). The passivity breakdown potential was taken as the potential for which the current density reached 20 $\mu\text{A}/\text{cm}^2$ (E_{20}). Electrochemical tests show that alloy 22 was susceptible to localized (crevice) corrosion at applied anodic potentials in pure concentrated chloride solutions such as sodium chloride (Ref 65, 73, 75) and calcium chloride (Ref 56, 70, 76). However, when nitrate was added to the chloride containing solution, the susceptibility of alloy 22 to crevice corrosion decreased or disappeared (Ref 56, 60, 69, 70). For example, the crevice repassivation potential of welded alloy 22 in

Fig. 2 Corrosion rates for alloy 22 crevice coupons in simulated acidified water (SAW), simulated concentrated water (SCW), and simulated dilute water (SDW). The tests were carried out for 5+ years at the Long Term Corrosion Test Facility at Lawrence Livermore National Laboratory. Source: Ref 58

0.5 M NaCl at 95 °C (205 °F) was 0 V (SCE) (Ref 60). When 0.05 M nitrate was added ($\text{Cl}^-/\text{NO}_3^- = 10$) the crevice repassivation potential remained unchanged; however, when 0.1 M and higher nitrate concentration was added ($\text{Cl}^-/\text{NO}_3^- = 5$), the crevice repassivation potential was near 350 mV (SCE) and the alloy was free from crevice corrosion (Ref 60). In another study, the susceptibility of alloy 22 to crevice corrosion was tested as a function of temperature and pH in 5 M lithium chloride (LiCl) containing different amounts of oxyanions (sulfate and nitrate). It was reported that as the ratio $\text{Cl}^-/(\text{NO}_3^- + \text{SO}_4^{2-})$ decreased from 100 to 10 to 1, the susceptibility to crevice corrosion decreased (Ref 69). In a third study, it was reported that the breakdown potential of alloy 22 in 5 M CaCl_2 solution at 90 °C (195 °F) was 0.195 V (SSC); however, when 0.5 M calcium nitrate, $\text{Ca}(\text{NO}_3)_2$, was added ($\text{Cl}^-/\text{NO}_3^- = 10$), the breakdown potential increased to 0.76 V (SSC) and the alloy was free from localized corrosion (Ref 56). Figure 3 shows the cyclic potentiodynamic polarization for alloy 22 in 5 M CaCl_2 at three different temperatures. As the temperature increases, both the breakdown and repassivation potential decreases. The difference in the breakdown potentials between 105 and 75 °C (220 and 165 °F) is smaller than between 75 and 45 °C (165 and 115 °F) suggesting that there is a threshold temperature below 75 °C (165 °F) on the susceptibility of alloy 22 to localized corrosion as measured using the CPP technique (Fig. 3) (Ref 70). Figure 4 shows the E_{corr} (after 24 h) of alloy 22 both in 5 M CaCl_2 and in 5 M $\text{CaCl}_2 + 0.5 \text{ M Ca}(\text{NO}_3)_2$ as a function of the

testing temperature (Ref 70). The E_{corr} of alloy 22 in pure CaCl_2 solutions does not change with the temperature; however, in the brine that contains nitrate, E_{corr} appears to increase slightly at the highest tested temperature. Figure 4 also shows that the repassivation potential (ER1) of alloy 22 increases when nitrate is added to the solution. For example, at 90 °C (195 °F), for pure chloride solution ER1 is approximately -150 mV (SSC) and for the solution with nitrate approximately +400 mV (SSC). Also, for each solution, there are two different slopes for ER1 depending on the temperature range.

Alloy 22 may be susceptible to crevice corrosion, but only under highly aggressive environmental circumstances such as high chloride concentrations at high temperature and applied anodic potentials. In pure chloride solutions, the crevice repassivation potential (e.g., ER1) decreases as the temperature (T) and the chloride concentration $[\text{Cl}^-]$ increases following the relationship (Ref 66):

$$ER = A - BT - C \log [\text{Cl}^-] \quad (\text{Eq 1})$$

where A , B , and C are constants.

Figure 5 shows that the appearance of the corroded metal under the crevice former is with grain-boundary etching, typical of the corrosion of alloy 22 in hot hydrochloric acid (HCl) solutions. Pitting corrosion is seldom observed in alloy 22, and the variables controlling pitting corrosion are unclear. Surface condition could be a factor that may trigger pitting corrosion.

In general, the E_{corr} of alloy 22 is always below the E_{crit} for localized corrosion. For

example, Fig. 4 shows that for 24 h tests, E_{crit} (ER1) in each solution was always higher than E_{corr} , that is, alloy 22 would remain free of localized attack at its free corroding potential. In a few circumstances, after long exposure times in aerated electrolytes, E_{corr} of alloy 22 could raise to a potential value comparable to E_{crit} . The fact that E_{corr} may reach the value of E_{crit} is a necessary but not a sufficient condition for crevice corrosion. The occurrence of crevice corrosion will depend not only on the environmental conditions such as chloride to nitrate ratio and temperature but also on the crevice geometry (tightness) and nature of the crevicing material. Crevice corrosion can be initiated in alloy 22 using potentiostatic tests. Results show that crevice corrosion propagated for the first few hours of testing, but after a couple of days crevice corrosion slowed down and seemed to die since the total measured current density reached the passive current density of the alloy in polarization studies. Mechanisms of crevice corrosion initiation, growth, and arrest (stifling) still need to be studied in detail.

Environmentally Assisted Cracking of Alloy

22. Environmentally assisted cracking is a phenomenon by which certain ductile metallic materials lose ductility in the presence of tensile stresses in specific corrosive environments. That is, for EAC to occur, the simultaneous presence of three factors must be present. These are (a) a susceptible microstructure, (b) tensile stresses, and (c) an aggressive environment. If one or more of these variables is eliminated, EAC will not occur. Mill annealed (wrought) alloy 22 is highly resistant to EAC in most environments,

Fig. 3 Cyclic potentiodynamic polarization for alloy 22 (UNS N06022) in deaerated 5 M CaCl_2 solutions at different temperatures. The higher the temperature, the lower the breakdown potential (E_{200}) or repassivation potential (ER1)

Fig. 4 Parameters from cyclic potentiodynamic polarization for alloy 22 (UNS N06022) in deaerated 5 M CaCl_2 and in 5 M $\text{CaCl}_2 + \text{Ca}(\text{NO}_3)_2$ solutions as a function of temperature. At each temperature (for example at 75 °C, or 165 °F), the repassivation potential (ER1) is raised when nitrate is added to the solution. Source: Ref 70

including acidic concentrated and hot chloride solutions (Ref 74, 77–80). Alloy 22 did not suffer EAC when it was tested in 14 M Cl^- (as magnesium chloride, $MgCl_2$) at 110 °C (230 °F) and 9.1 M $LiCl$ at 95 °C (205 °F) under controlled potential. Wedge opening loaded double cantilever beam (DCB) and compact tension (CT) specimens at stress intensities in the range 32 to 47 $MPa\sqrt{m}$ (29 to 43 $ksi\sqrt{in.}$) were used for times as long as 52 weeks (Ref 75, 77, 80). Similarly, U-bend specimens of alloy 22 did not suffer EAC when exposed to 45% $MgCl_2$ at 154 °C (309 °F) for up to 6 weeks (Ref 78). Slow strain rate tests (SSRT) of alloy 22 at a $1.6 \times 10^{-6} s^{-1}$ strain rate at the (E_{corr}) in 4 M $NaCl$ at 98 °C (208 °F), saturated $CaCl_2$ ($>10 M$ Cl^-) at 120 °C (250 °F) and 1% lead chloride ($PbCl_2$) at 95 °C (205 °F) did not show a loss of ductility or secondary cracking (Ref 79). Welded and wrought U-bend specimens of alloy 22 and other five nickel-base alloys exposed for more than 5 years to multiionic solutions that represent concentrated groundwater of pH 2.8 to 10 at 60 and 90 °C (140 and 195 °F) were free from EAC (Ref 81).

Even though alloy 22 is resistant to EAC in concentrated hot chloride solutions, it may be susceptible under other severe environmental

conditions. For example, alloy 22 U-bend specimens suffered transgranular EAC when they were exposed for 336 h to aqueous solutions of 20% hydrogen fluoride (HF) at 93 °C (199 °F) and to its corresponding vapor phase (Ref 82). The liquid phase containing HF was more aggressive than the vapor phase. High concentrations of wet HF is not a representative environment for underground conditions since calcium fluoride (CaF_2) would form and this salt is rather insoluble. The susceptibility of alloy 22 to EAC was tested at the E_{corr} in aerated BSW at 110 °C (230 °F) (Ref 83, 84). This BSW multi-ionic solution is a version of concentrated solutions that might be obtained after evaporative tests of Yucca Mountain groundwaters. Using the reversing direct current potential drop technique, it was reported that the crack growth rate was $5 \times 10^{-13} m/s$ ($16.4 \times 10^{-13} ft/s$) in a 20% cold-worked specimen loaded to a stress intensity of 30 $MPa\sqrt{m}$ (27.3 $ksi\sqrt{in.}$). The testing conditions used were highly aggressive and, in spite of that, the measured crack growth rate was near the detection limit of the system (Ref 83, 84). Slow strain rate tests were performed using MA alloy 22 specimens in SCW and other solutions as a function of the temperature and applied potential (Ref 79, 85, 86). Alloy 22 was

found susceptible to EAC only in hot SCW solution at anodic applied potentials approximately 300 to 400 mV more positive than E_{corr} . In the anodic region of potentials, the susceptibility to EAC decreased as the temperature decreased. Figure 6 shows the dependence of the time to failure of alloy 22 on temperature when strained at high anodic potentials in SCW solution. Environmentally assisted cracking was not observed for specimens strained in SCW at ambient temperature. Figures 7 and 8 show the influence of temperature for the same applied potential of +400 mV (SSC). While at 86 °C (187 °F), there was secondary cracking and almost no necking (Fig. 7), at 50 °C (120 °F) the secondary cracking disappeared while necking was prominent (Fig. 8). While alloy 22 suffers SCC in hot SCW solution at high anodic potentials using the SSRT technique, cracking did not occur under similar testing conditions using the U-bend or constant deformation technique (Ref 87). Alloy 22 was also slightly susceptible to EAC in SCW at –1000 mV (SSC), especially at ambient temperature. Fluoride seems more detrimental than chloride for the EAC resistance of alloy 22 (Ref 86).

Environmentally assisted cracking is unlikely to initiate and grow in alloy 22 in the repository conditions where the only stresses are residual stresses from fabrication (forming and welding) or from rock fall impact on the container. Nevertheless, it is planned to further mitigate the possibility of EAC by putting compressive stresses on the container surface (Ref 6). Assembly welds made during the container fabrication are expected to be solution annealed to remove residual stress and restore the alloy homogeneity in the welded region. This will help to minimize EAC initiation. Stress mitigation processes around the final closure weld (top lid onto the container body, filled with the waste form) have also been proposed. The two processes under active consideration are laser peening and low plasticity burnishing (Ref 6).

Laser peening produces a compressive stress layer on the welded waste package surface, and with optimization of the process, this layer may achieve ~3 mm (~0.12 in.) in depth. Burnishing is a mechanical process by which the compressive stresses on the surface are applied via a rolling ball.

Corrosion Behavior of Titanium Alloys

Titanium grade 7 (Ti Gr 7 or R52400) has been chosen to fabricate the detached drip shield for the repository in Yucca Mountain. The presence of the drip shield would deflect early water seepage from the containers. This drip shield would also deflect rock fall from the containers. Ti Gr 7 belongs to a family of commercially pure and modified titanium alloys especially designed to withstand aggressive chemical environments. The superior corrosion resistance of titanium and titanium alloys is due to a thin, stable, and tenacious oxide film that forms rapidly in air and water, especially under oxidizing conditions. Titanium alloys have a broad range of application as corrosion-resistant materials. This includes seawater, wet chlorine, chlorinated organic compounds, and oxidizing acids (e.g., nitric and chromic acids) (Ref 72, 88). Some of

the media in which titanium should not be used include hydrofluoric acid, dry chlorine, and hot pure sulfuric acid solutions. The family of titanium corrosion-resistant alloys includes grades from 1 to 34 (Ref 89). Ti Gr 2 (R50400) is commercially one of the more popular grades. Other, more corrosion-resistant grades, which are the focus of the current studies, include Ti Gr 7 (R52400), Ti Gr 16 (R52402), and Ti Gr 12 (R53400) (Table 3). These three grades contain small amounts of alloying elements that improve the corrosion resistance of these alloys. For example, Ti Gr 7 contains 0.12 to 0.25% Pd, Ti Gr 16 contains 0.04 to 0.08% Pd, and Ti Gr 12 contains 0.2 to 0.4 Mo and 0.6 to 0.9% Ni (Ref 89). A detailed review of the general, localized, and environmentally assisted cracking behavior of Ti Gr 7 and other titanium alloys relevant to the application in Yucca Mountain has addressed, among other topics, the effect of alloyed palladium, the properties of the passive films, and the effect of radiation (Ref 41).

General and Localized Corrosion of Titanium Alloys. The general corrosion resistance of Ti Gr 7 is superior to that of Ti Gr 12; however, this effect is more noticeable under reducing conditions due to the beneficial effect of palladium (Ref 88, 90). Corrosion-rate data for Ti Gr 16 are scarce. Some titanium alloys

may be susceptible to crevice corrosion under certain conditions; however, these alloys are practically immune to pitting corrosion in halide-containing environments under most practical applications. It has been suggested that the susceptibility to crevice corrosion is due to the formation of a low pH reducing solution under the occluded conditions, where the corrosion rate of titanium is higher than in oxidizing conditions (Ref 91). Halide- and sulfate-containing solutions may induce crevice corrosion in titanium at temperatures higher than 70 °C (160 °F) (Ref 91). Anodic polarization of Ti Gr 7 in chloride- and fluoride-containing solutions at 95 °C (205 °F) have shown that the presence of fluoride produces significantly higher current densities at potentials above the corrosion potential (Ref 92, 93). The presence of fluoride may have also rendered Ti Gr 7 more susceptible to crevice corrosion under anodic polarization (Ref 92).

As with alloy 22, titanium alloys Ti Gr 7, Ti Gr 16, and Ti Gr 12 are being tested in the Long Term Corrosion Test Facility at LLNL. Weight loss, creviced, and U-bend specimens were exposed to three different electrolyte solutions simulating concentrated groundwater for more than 5 years both at 60 and at 90 °C (140 and 195 °F) in the vapor and liquid phases of these solutions. Table 8 shows the corrosion rates calculated by weight loss in the nonstressed specimens (Ref 94). Each titanium alloy exhibited some discoloration (due to the possible formation of an oxide film). Ti Gr 7 generally exhibited the lowest corrosion rates irrespective of temperature or solution type while Ti Gr 12 generally exhibited the highest corrosion rates (Fig. 9) (Ref 94). The specimens immersed in the concentrated alkaline solution (SCW) exhibited the highest corrosion rates regardless of alloy composition. Specimens immersed in the acidified solution and the dilute alkaline solution exhibited significantly lower, and similar, corrosion rates. Ti Gr 12 generally exhibited higher corrosion rates at 90 °C (195 °F) than 60 °C (140 °F). There did not appear to be a temperature dependence on corrosion rate for Ti Gr 7 or Ti Gr 16. For all alloys, there did not appear to be any weld effect on the corrosion rates (Ref 94). In a previous corrosion-rate study by weight loss of Ti Gr 7 in BSW solution at 105 °C (220 °F), no effect was also reported between nonwelded and welded coupons (Ref 61).

Environmentally Assisted Cracking of Titanium Alloys. Titanium and titanium alloys may suffer EAC such as hydrogen embrittlement (HE) and SCC. Embrittlement by hydrogen is a consequence of absorption of atomic hydrogen by the metal to form hydrides (Ref 91, 95, 96). This may happen in service when the titanium alloy is coupled to a more active metal in an acidic solution. A critical concentration of hydrogen in the metal may be needed for HE to occur (Ref 41, 95). The few environments that can induce SCC in titanium are absolute (anhydrous) methanol, red-fuming nitric acid, and nitrogen tetroxide (Ref 91, 97). A few percent

of water in the environments mentioned previously would inhibit the SCC in titanium.

Regarding the application for the Yucca Mountain repository, slow strain rate tests ($3.3 \times 10^{-6} \text{ s}^{-1}$) were performed using smooth specimens of Ti Gr 7 and Ti Gr 12 in 5 wt% NaCl, pH 2.7, at 90 °C (195 °F) at the applied potentials between 0 and −1.2 V (SSC) (Ref 98). It was reported that for Ti Gr 12 (R53400), as the potential decreased the reduction of area at rupture decreased from 40% at 0 V to approximately 15% at −1.2 V (SSC). This behavior was attributed to a HE mechanism due to the formation of hydrides. Under the same tested conditions the reduction of area of Ti Gr 7 (R52400) remained approximately constant at near 50%; that is, Ti Gr 7 was more resistant to EAC than Ti Gr 12. After straining, both Ti Gr 7 and Gr 12 exhibited shallow secondary cracks at all of the tested potentials (Ref 98). The critical concentration of hydrogen to produce HE was calculated to be higher in palladium-containing titanium alloys (such as Ti Gr 7) than for titanium alloys without palladium (such as Ti Gr 12) (Ref 99). It was also anticipated that an enhanced passive corrosion rate of Ti Gr 7 (for example, in an environment containing fluoride ions) could produce enough hydrogen to reach the critical concentration in the metal to cause HE (Ref 99). Intergranular stress-corrosion cracking (IGSCC) changing to transgranular stress-corrosion cracking (TGSCC) was reported on one U-bend specimen of Ti Gr 7 exposed for 155 days in a solution containing 35,500 ppm chloride and 1900 ppm fluoride, pH 6.5, at 105 °C (220 °F) (Ref 100). Stress-corrosion cracking was reported in Ti Gr 7 specimens subjected to constant load tests in a concentrated groundwater solution of pH ~10 at 105 °C (220 °F) (Ref 101). Results from a up to 5 year immersion testing at 60 and 90 °C (140 and 195 °F) of U-bend specimens made of wrought and welded Ti Gr 7 and Ti Gr 16 alloys showed that these alloys were free from EAC in multionic solutions that could be representative of concentrated groundwater at Yucca Mountain (Ref 90). Welded Ti Gr 12 U-bend specimens suffered EAC in SCW liquid at 90 °C (195 °F). Under the same conditions, nonwelded Ti Gr 12 was free from cracking (Ref 90).

Summary

The following major points are examined in this article:

- Many countries are developing geologic repositories for their high-level nuclear waste.
- Most of the repositories in the world are planned to be in stable rock formations (e.g., granite) below the water table (saturated). The United States is studying a repository above the water table (unsaturated).
- The repositories will consist of a stable geologic formation within which engineered barriers will be constructed. The main part of

Fig. 9 Corrosion rates for Ti Gr 12, Ti Gr 16, and Ti Gr 7 crevice coupons in simulated concentrated water solution. Ti Gr 12 had the highest corrosion rates Source: Ref 94

the engineered barrier is the container of the waste.

- The containers are in general designed as double-walled metallic cylinders.
- From the corrosion point of view, most repositories will deal with reducing redox potentials with the exception of the U.S. repository, which will have a natural oxidizing environment.
- Copper, titanium, stainless steels, and even carbon steels were determined to be suitable materials for the reducing repositories.
- Alloy 22 and Ti Gr 7 are being characterized for the mostly dry oxidizing environment of the U.S. repository.
- Materials for the engineered barriers are constantly being evaluated for general corrosion, localized corrosion, and environmentally assisted cracking resistance.
- The metals are studied under different metallurgical condition, for example, mill annealed, welded, thermally aged, and so forth.
- Environmental variables that affect corrosion behavior include the concentration and type of the aqueous electrolytes at the site (different soluble salts), temperature, redox potential, radiation, microbial activity, and so forth.

Introduction to Corrosion in Fossil and Alternative Fuel Industries

John Stringer

THE PRIMARY FOSSIL FUELS are generally defined as coal, oil, natural gas, tar sands, and shale oil. These can be further subdivided, in terms of the quality of the fuel. For example, coal can be anthracite, bituminous coal, subbituminous coal, or lignite; further classification is possible. Ultimately, a fuel is burnt producing heat, and the heat is then directed to some useful purpose. This purpose might be the generation of electricity, process heat for chemical industry, domestic heating, and so forth.

Fuels

The primary fuels as produced generally contain a number of impurities. In the case of coals, these impurities can be divided in two classes: physical impurities, such as mineral species, which are chemically inert (silica is an example), and chemical impurities, such as sulfides, which undergo modifications during combustion.

Both of these classes of impurities can result in environmental problems. The incombustible physical impurities generate products called ash: the large particle forms of this can be collected and must be disposed of; the small particles may become entrained in the off-gases and may become an environmental hazard with adverse effects on the pulmonary system. The chemical impurities can result in the release of atmospheric impurities such as sulfur oxides and nitrogen oxides, which have been shown to be health hazards, and may also cause damage to other components of the biota, for example trees. In addition, the chemical impurities play a major role in the corrosion of the fuel systems.

The alternative fuels are various; wood, and specifically wood waste from the timber industry, is a major resource. Agricultural wastes are also important, and there are now plants and trees that are being specifically grown for fuel use. Various wastes, such as industrial wastes and municipal solid wastes (MSWs), are increasingly being used as fuels. These fuels also contain impurities of one kind or another; waste wood,

for example, can be contaminated with salts from seawater.

The physics and chemistry of these alternative fuels cover a wide spectrum, and even a specific alternative fuel can have a wide range of compositions; MSW is an obvious example. Increasingly, primary fuels are being processed before use. Treatment of coals has been a common practice for many years; for example, many of the coals as mined may contain unacceptably large fractions of mineral species, and this may be reduced at the minehead before shipping to the customer, or at the customer's site before use. In other cases, the final use for a fuel may be better served by a liquid or a gas, and solid fuels may be processed for this purpose. In the case of petroleum-based fuels also, the quality of the required fuel requires adjustment, and this too has been done for many years. The higher boiling-point fractions, which have higher carbon/hydrogen ratios, also have higher viscosities; these are separated by distillation and then hydrogenated to produce a lighter hydrocarbon. The hydrogen for this is generated by steam reformation of the lowest fractions. Coals have been gasified for many years; currently the preferred approach involves entrained gasification at elevated temperatures, with the incombustible fraction forming a slag that is water-quenched in the bottom of the gasifier to allow easy removal by lock-hoppers. The high-temperature gas product is cooled using a heat exchanger within the gasifier, and the gaseous impurities containing sulfur and chlorine are removed from the product stream. The initial product gas may contain hydrogen and carbon monoxide, but this can be shifted to methane to produce a synthetic natural gas. Gasification of the alternative fuels is also possible, with the aim of producing a more practical fuel and controlling harmful impurities. In some cases, a liquid fuel that can be substituted for gasoline is required; biomass conversion to ethanol is an example that has been used for a number of years, and this approach appears to be increasing in importance. Liquefaction of coal has also been a research topic for a long time, and for some years there was an active program in

hydrogenation of coal for this purpose. However, although it can be done, the program in the United States was abandoned for economic reasons some years ago.

The control of the emissions to attain regulatory requirements is an important part of the overall systems. In some cases, the modification of the primary fuel mentioned will reduce or even eliminate the impurities, as indicated previously, but often these become concentrated in the by-product, and disposal of this may itself present significant problems.

Energy Conversion

Generally, the chemical energy in a fuel is transformed by oxidation. In the majority of cases, this involves combustion, and the objective of the combustion system is to attain the maximum conversion possible. Typically, this involves attaining the best possible mixing between the fuel and the oxidant (usually air). For the solid fuels, this normally requires reducing the as-received fuel to a particulate form; this is then injected into the combustion chamber through a nozzle in which some or all of the combustion air is used to transport the fuel prior to ignition. The nozzle itself is designed to promote the mixing, and ignition occurs within the combustion chamber at or close to the end of the nozzle. For liquid fuels, the process is much the same, but the reduction in the fuel particle size is usually much simpler. For gaseous fuels, it is still important to achieve good mixing prior to combustion.

There are other approaches. The most significant of these is fluidized bed combustion, in which the solid fuel (or, less commonly, liquid fuel) is injected into a bed of particles through which air is blown from beneath; at a certain flow velocity the bed becomes fluidized and behaves like a liquid; both the chemical mixing and the heat transfer within bed is extremely efficient. The combustion of the fuel takes place within the bed, and part of the heat of combustion may be removed by an in-bed heat exchanger to maintain a constant temperature within the bed. The fuel

particle size does not have to be so fine as in the system described previously, and in addition it is possible to achieve the chemical removal of some of the environmentally unacceptable impurities by the use of additives within the bed. There are some corrosion issues specific to this technology; these are not discussed here.

There are other ways of converting the energy, most specifically by using an electrochemical approach. This is the method used in a fuel cell, in which the chemical energy is directly converted to electrical energy. For most of the fuel cells currently being produced, the fuel must be hydrogen, although this can be produced from hydrocarbon fuels by a reformer within the power plant itself. The efficiency of the conversion using this approach is not limited by the thermodynamic Carnot restrictions, and fuel cells have been made to operate at room temperature or temperatures as high as 1100 K. There are a number of corrosion issues in these systems.

Following the combustion, the sensible heat is contained in the combustion gas, and in the majority of cases the useful energy has to be removed from this. In the case of domestic heating, or similar end uses such as product drying, the desired product is a clean, relatively low-temperature heat, and this can be gas (for drying, or forced gas domestic heating systems) or warm water, again for heating systems. The conversion from a relatively hot combustion gas with a number of unacceptable impurities to this clean, lower-temperature product is achieved by a heat exchanger, with the hot dirty gas on one side and the clean, warm product on the other side. The emission from the combustion gas side will be a much cooler gas, with a temperature hopefully only a little above the product temperature. One of the issues with these systems can be related to the dew point on the dirty gas side; generally, it is important to avoid condensation within the heat exchanger itself. The exhaust must also satisfy the environmental requirements and may require treatment to achieve this. The details of the treatment, and the problems involved, will depend very much on the system and particularly on the fuel used.

More generally, the objective is to convert the thermal energy to mechanical energy, and this is done with a heat engine. In most cases, this involves expanding a hot, high-pressure gas through an engine to produce a mechanical result that is most often the rotation of a shaft. The most common example is the automobile engine, in which gasoline and air are drawn through a valve to a mixing nozzle into a cylinder by a piston; the mixture is then compressed by the piston rising in the cylinder. The compressed mixed gases are then ignited by a spark and explode, driving the piston down. The piston is attached to a crankshaft, rotating a shaft; as the shaft rotates a valve opens, allowing the combustion gas exhaust to escape. Here, the combustion gas is the "working fluid," and the compression is achieved by the piston in the cylinder. This is called the Otto cycle.

In the case of a steam turbine system, the combustion gas is used to boil water inside a

heat exchanger; the compression is achieved by pumping the inlet water. The compressed steam is then allowed to expand through a turbine, and it is condensed by a condenser at the turbine exhaust; the condensate is then recycled to the boiler. This called the Rankine cycle. The steam is the working fluid, and this is an example of an indirect working fluid.

A gas turbine (also called a combustion turbine) is generally a direct cycle; air is compressed by a turbine; at the exit of this, fuel is injected into the compressed air in a combustion chamber, and the hot gas is expanded through another turbine. This drives the compressor, and this may also power the driveshaft. The working fluid in this case is the combustion gas. This is called the Brayton cycle.

Efficiency

The efficiency of a heat engine, μ , is restricted by thermodynamic principles originally outlined by Carnot, and it is determined by the maximum temperature in the thermodynamic cycle T_{\max} , and the minimum temperature, T_{\min} . Here, both temperatures are absolute. The ideal Carnot efficiency μ_C is:

$$\mu_C = (T_{\max} - T_{\min})/T_{\max}$$

The maximum and minimum temperatures in a cycle are determined at the entrance and exit of the working component: thus, in the case of the ranking cycle it is the steam temperature at the entrance to the turbine and the temperature at the exit of the turbine, which is close to the condenser entry temperature. For the majority of the steam turbines used to generate electricity in the United States at the moment, these temperatures are 811 and 300 K; μ_C is thus 0.63. However, a real system is not ideal, and the actual efficiency in a practical system is closer to 0.38. In the case of a combustion turbine the maximum temperature is considerably higher, but the minimum cycle temperature, which is that of the turbine exhaust, is also considerably higher. The cycle efficiency turns out to be more or less the same. However, if the exhaust gas from a combustion turbine is used to raise steam to power a steam turbine, the overall efficiency of the system is considerably higher. This is called a combined cycle, and efficiencies as high as 0.60 have been achieved.

Since 1987 there have been a number of significant changes in the system requirements for the fossil and alternative fuel industries. These essentially fall into three groups: the first is a desire to improve the overall efficiencies of the overall energy conversion, the second is a need to accept a wider range of fuels, and the third is to achieve much improved control over the environmental implications.

The first issue essentially requires increasing the temperature difference across the cycle. For a simple Rankine cycle, there is usually virtually no possibility of reducing the minimum cycle temperature, so this really means increasing the

steam temperature at the turbine inlet. Achieving this results in a need for a different suite of materials for the high-temperature parts of the system; this is particularly true for the Rankine cycle machines, since the Brayton cycle turbines used for power generation have inlet temperatures at the power turbine still less than those in aircraft engines, so there are materials capable in principle of meeting these requirements. It is not, of course, quite as simple as this, because the component sizes are larger, and this means that some of the materials used in aviation engines cannot be used for the land-based engines. These new materials requirements arise primarily for mechanical property reasons, and the issues that arise for achieving adequate corrosion resistance combined with the mechanical criteria present further problems. In some cases, this may require coatings or claddings. The requirements of most concern are on surfaces in contact with the combustion gases, but it can be expected that the steam-side surfaces may also experience enhanced attack; issues such as the exfoliation of steam-side oxide may become more important.

The second issue has two aspects. One is blending of fuels: a high sulfur coal with a low sulfur coal, for example, or municipal solid waste with coal. The second is the ability to switch fuels: having a gas turbine able to switch from natural gas to oil, for example.

The third issue involves a number of aspects. One of particular importance at the moment is controlling combustion to reduce NO_x emissions. In the case of a large, coal-fired utility boiler, for example, if the coal is combusted in the boiler at low excess air, or even at sub-stoichiometric air in the vicinity of the fuel nozzles, with the balance of the air added higher in the boiler, the emissions can be reduced considerably. However, the consequence is that the lower water-wall tubes in the boiler experience a significantly more corrosive environment, associated with the impact of uncombusted coal particles and unoxidized pyrite particles. Another approach is to replace the direct firing of coal by the use of a gasifier before the combustion; as indicated previously, the removal of impurities, including ash, is easier, but the corrosion problems in the boiler are replaced by the corrosion issues in the gasifier. The corrosion issues in the systems used to remove the impurities are also different.

The high-temperature corrosion problems in most of these systems involve two principal mechanisms: mixed-gas corrosion—typically involving conditions that may be sulfidizing and oxidizing, or carburizing and oxidizing—and molten salt accelerated corrosion. In the latter case, alkali metals—sodium, and potassium—in the impurities are often vectors in the attack. In the cases of petroleum-based fuels, vanadium species may be important.

All of the heat engines are designed to make the most use of the heat, and this means that there are several "warm-water" streams in the systems. Some of these are very pure waters, as is the case

in the recycle of the boiler condensate; some of them are more or less impure “gray” waters. There are important corrosion issues in these locations also. The condensers are typically cooled with water that may come from local rivers or the ocean, and the flows are considerable; it is generally impossible to undertake any

treatment of these waters. The problem of process condensates on the combustion gas side has been mentioned previously, and one obvious and important example is condensation in the exhaust stack or immediately downstream of the stack. These can result in both environmental issues and corrosion damage.

It is apparent that there are a wide range of corrosion-related issues in the utilization of fossil fuels and alternative fuels, and recent studies have given some good estimates of the economic impact of these issues. The following articles describe a number of these problems in more detail.

High-Temperature Corrosion in Gasifiers

Wate Bakker, Electric Power Research Institute

INTENSIVE DEVELOPMENT of gasification technology has been carried out since the early 1970s (Ref 1–3). At present (2005), several commercial- or nearly commercial-scale coal-gasification combined-cycle (CGCC) plants are in operation worldwide. These include plants based on the Texaco and Dow processes in the United States, a plant based on the Prenflo (Krupp-Uhde) process in Spain, and a plant based on the Shell process in the Netherlands. All present plants include entrained slagging gasifiers and cold-gas cleanup equipment. In this type of gasifier, the fuel—coal, petroleum coke, or heavy oil bottoms—are pulverized and fed to the gasifier in dry or slurry form. Gasification is carried out at very high temperatures, above the melting point of the mineral matter in the fuel, usually at 1300 to 1600 °C (2370 to 2910 °F). The raw hot gas, consisting mainly of CO and H₂, with H₂S as the major corrosive impurity, is cooled in syngas (synthetic gas) coolers and then water quenched to remove particulates and water-soluble impurities such as NH₃ and chlorides. After quenching, H₂S is removed in one of several commercially available gas-purification systems, for instance, the Selexol process. The purified gas is then fed to a gas turbine combined-cycle plant for combustion and electricity generation. Figure 1 shows a schematic of such a plant, which is quite complex.

Several corrosion and erosion problems have occurred in various plants, mostly at the pilot plant stage. These include coal slurry erosion and corrosion in feed systems, refractory corrosion and erosion in gasifiers, high-temperature corrosion in syngas coolers, and aqueous corrosion in downstream and gas-purification equipment. Most of the problems found are not unique to gasifiers, but have been encountered elsewhere and have been resolved using existing technology. However, high-temperature corrosion in syngas coolers is unique to gasifiers; in these systems there are interactions that occur between the materials of construction and various impurities present in coal as well as other fuels. Therefore, this article concentrates on high-temperature corrosion in syngas coolers.

Details on operating conditions in syngas coolers are provided in Refs 1 and 4. The composition of the raw syngas depends on the

gasification process used and the fuel composition, especially its sulfur and chlorine content. The syngas composition of processes with water-coal slurry systems is typically (vol%) 35 to 45 CO, 10 to 15 CO₂, 27 to 30 H₂, 15 to 25 H₂O, 0.2 to 1.2 H₂S, and 50 to 500 ppm HCl; for a dry-fed gasifier, the CO content of the gas is considerably higher (62 to 64%), while the CO₂ and H₂O contents are generally less than 4%. Thus the partial oxygen pressure (p_{O_2}) of a syngas from slurry-fed gasifier is considerably higher than that from a dry-fed gasifier. The syngas composition reflects the high-temperature equilibrium composition at 1300 to 1500 °C (2370 to 2730 °F), while the heat exchangers operate at 300 to 600 °C (570 to 1110 °F). This makes it difficult to calculate p_{O_2} and p_{S_2} values, since the gases are not in equilibrium at the metal temperature (Ref 1). Heat-exchanger syngas operating temperatures in present gasifiers are generally less than 450 °C (842 °F), partly due to high-temperature corrosion issues that indicate that the use of higher heat-exchanger

temperatures with current designs are not cost effective.

Corrosion Mechanism and Laboratory Studies

The major corrosion mechanism in syngas coolers is sulfidation for low-alloy steels and sulfidation/oxidation for more highly alloyed chromium-containing materials. Due to the low p_{O_2} and relatively high p_{S_2} of the raw syngas, the sulfidation rate of carbon and low-alloy steels is too high to allow the use of these low-cost materials. This is shown in Fig. 2, which contains information from laboratory as well as plant studies, with good agreement between the two. It is further observed that the corrosion rate of low-alloy steels appears largely independent of the chlorine content of the coal. The plant data in Fig. 2 were obtained from coals or coal-derived fuels with chlorine contents ranging from 0.05 to

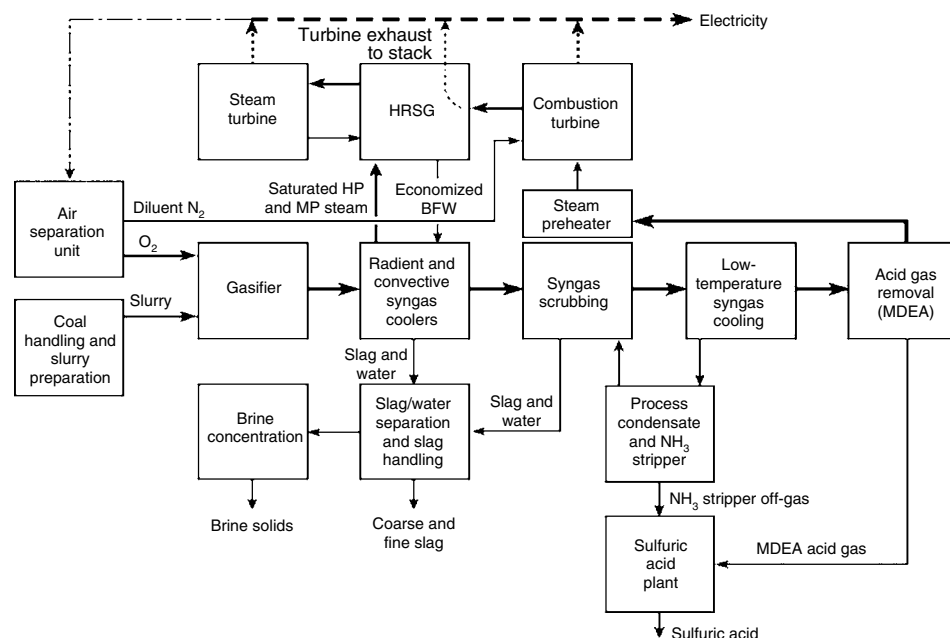

Fig. 1 Coal-gasification combined-cycle CGCC power plant. HRSG, heat recovery steam generator. Acid gas removal uses MDEA, methyldiethanolamine

0.3%, resulting in 100 to 600 ppm HCl in the syngas (Ref 1). Laboratory tests confirm that HCl contents in this range do not increase corrosion rates, at least not under the highly reducing conditions present in gasifiers.

Due to the unacceptably high corrosion rates of low-alloy boiler steels, stainless steel heat-exchanger tubes, coatings, or claddings must be used to provide low corrosion rates. A complicating design factor is that some construction codes (such as those issued by the American Society for Mechanical Engineers) limit the use of certain stainless steels in water wetted service. Extensive laboratory corrosion studies on both model and commercial alloys have been reported earlier (Ref 1, 5) and are summarized here. All experiments were done under isothermal conditions. It was found that the corrosion rate of stainless steels containing 20% or more chromium with or without various minor alloying elements, such as silicon, aluminum, and titanium, did not simply increase with increasing p_{S_2}/p_{O_2} ratio of the syngas, but also depended on the HCl content of the syngas, the presence of chlorides in deposits, and alloy composition.

In the absence of HCl in the syngas, the corrosion loss indeed increases as a function of the p_{S_2}/p_{O_2} ratio as shown in Fig. 3 for alloys 800

Fig. 2 Corrosion of low-alloy steels in syngas environments. Plant data are compared to laboratory data for various hydrogen sulfide atmospheres.

Fig. 3 Corrosion losses of stainless steels as a function of partial pressure ratio $\log p_{S_2}/p_{O_2}$ without HCl. Laboratory test 540 °C (1000 °F), 600 h. Solid line, nickel alloy 800 (UNS N08800); broken line, type 310 stainless steel (UNS S31000)

(UNS N08800, Fe-20Cr-32Ni-0.35Al-0.35Ti) and 310 (UNS S31000, Fe-25Cr-20Ni). Corrosion rates are relatively low and parabolic reaction kinetics are usually observed (Ref 6, 7). Scanning electron microscopy/energy-dispersive x-ray analysis (SEM/EDAX) indicates that at high p_{S_2}/p_{O_2} ratios, a somewhat protective $FeCr_2S_4$ spinel is formed. At lower p_{S_2}/p_{O_2} ratios, this layer gradually changes to $FeCr_2O_4$. Below the $FeCr_2S_6$ layer, an inward-growing scale/precipitation zone is formed consisting of $FeCr_2(S,O)_4$ spinel, Cr_2O_3 , and iron-rich alloy remnants. This corrosion mechanism is labeled

type A corrosion and is schematically shown in Fig. 4.

When HCl is present in the syngas, the corrosion mechanism changes considerably, as is shown by a comparison of Fig. 5 to Fig. 3 (MA 956 is Fe-20Cr-4.5Al-Ti-Y, UNS S67956). Alloys with a relatively low chromium content such as alloy 800 now show a maximum corrosion rate at a p_{S_2}/p_{O_2} ratio of about 18, while alloys with a higher chromium content or similar oxide-forming alloying elements such as aluminum or silicon are relatively less affected by the addition of HCl to the gas. SEM/EDAX analysis

Fig. 5 Corrosion loss of three stainless steels as a function of partial pressure ratio $\log p_{S_2}/p_{O_2}$ with 400 ppm HCl. Laboratory test 600 h, 540 °C (1000 °F)

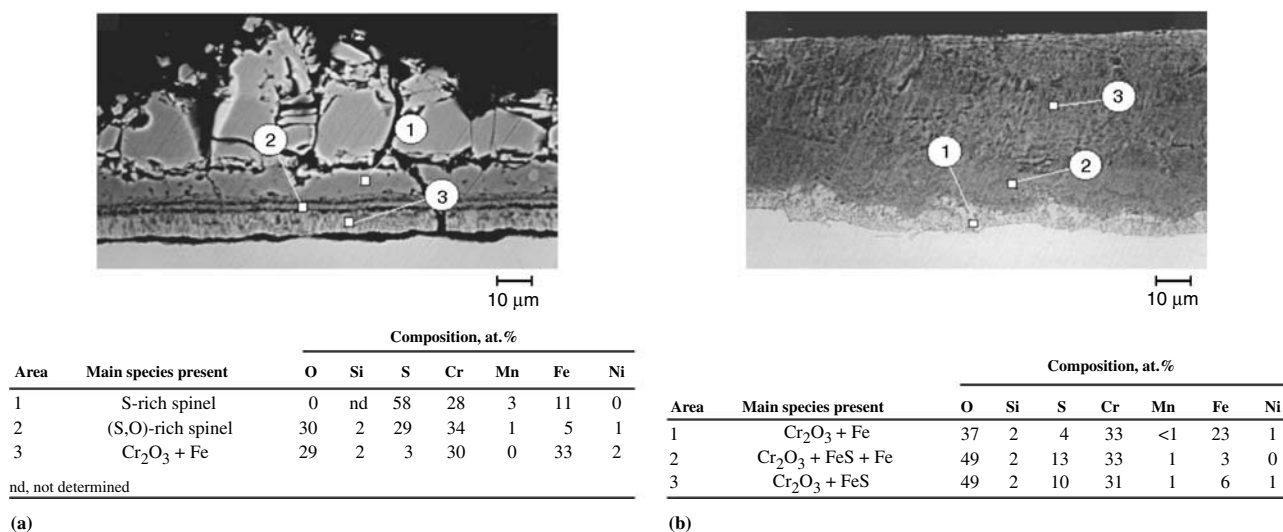

Fig. 6 Corrosion of type 310 (UNS S31000) stainless steel in syngas with 1200 ppm HCl. The electron dispersive spectroscopy (EDS) analysis is given for indicated areas along with the main species present. (a) Without deposit of 5% chloride, corrosion loss is 15 μm (0.6 mils). (b) With deposit of 5% chloride, corrosion loss is 86 μm . (a) and (b) Original magnification: 750 \times

of alloy 800 after exposure to a syngas with a $p_{\text{S}_2}/p_{\text{O}_2}$ ratio of about 18 and HCl content of 400 ppm indicated the absence of a protective FeCr_2S_4 scale. An outward-growing FeS-rich scale is present on top of an inward-growing porous Cr_2O_3 -rich scale containing $\text{Fe}(\text{Ni})\text{S}$, which appears nonprotective. This corrosion mechanism is labeled type B corrosion and is also schematically shown in Fig. 4.

The main difference between type A and B corrosion is that a protective FeCr_2S_4 is formed in type A. The absence of this protection in type B leads to higher corrosion rates. Further studies have shown that the onset of the less desirable type B corrosion depends on the amount of oxide-forming alloying elements in the alloy, the amount of HCl in the syngas, and the presence of chlorides in deposits, which probably increases the p_{Cl_2} near the metal surface. For instance, the corrosion loss of stainless steel 310 after 164 h exposure to syngas with a $p_{\text{S}_2}/p_{\text{O}_2}$ ratio of 18.5 and 1200 ppm is about 15 μm . However, when a deposit containing 5% chloride is present the corrosion loss increases to 86 μm and the corrosion mechanism changes from type A to type B (Fig. 6). Type A attack is shown in Fig. 6(a); here there is a sulfur-rich FeCr_2S_4 outer scale and a uniform inner-scale layer. Type B attack is shown in Fig. 6(b); here the outer scale is a mixture of sulfides and oxides and sulfur-rich nodules are observed at the metal/scale interface.

Aqueous corrosion during downtime can further increase overall corrosion rates in the presence of chloride-containing deposits. During downtime, the hygroscopic chlorides can migrate through cracks in the scale to the scale/metal interface and form an FeCl_3 -rich layer beneath the scale. During heatup, the FeCl_3 layer causes spalling of the protective Cr_2O_3 -rich scale and a new outward-growing FeS-rich scale and inward-growing Cr_2O_3 -rich scale is formed. This

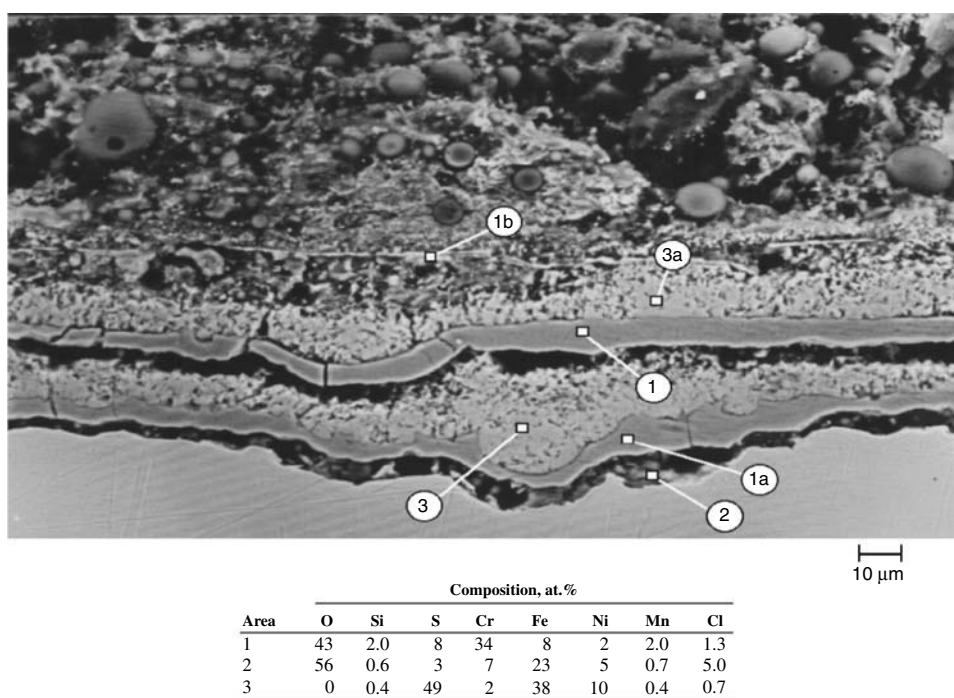

Fig. 7 Scanning electron microscopy image of type 310 (UNS S31000) stainless steel after 3 high temperature/downtime corrosion cycles. Details of the labeled layers are given in the text. Original magnification: 500 \times

sequence repeats itself during each thermal cycle. Figure 7 shows the scale microstructure after three 200 h high-temperature cycles and three 24 h downtime periods in humid air at 400 $^{\circ}\text{C}$ (752 $^{\circ}\text{F}$). During the first 200 h, the very thin protective layer 1b is formed, which spalls during downtime. During the next 200 h, a faster-growing, less protective layer (1) forms, which also spalls during downtime. Similarly, layer 1a forms during the third exposure. Layer 2 is the oxide- and chloride-rich layer formed

below the protective oxide-rich scale during downtime. Layers 3 and 3a are the nonprotective outward-growing FeS scales formed during the last two exposure periods.

From the laboratory experiments described previously, it is clear that the high-temperature corrosion of stainless steels in syngas environments is very complex and not readily predictable from simple gas/solid reaction mechanisms, especially when HCl is present in the gas and/or chlorides are in the deposit.

Long-Term Performance of Materials in Service

Laboratory tests are usually conducted at atmospheric pressure under isothermal conditions for a few hundred to a few thousand hours. Materials and components of electric power plants should last at least 100,000 h. In syngas coolers, components are also exposed to elevated pressures, 4 to 6 MPa (40 to 60 atm), with significant thermal gradients. Thus, laboratory tests are useful to determine corrosion mechanisms and guide alloy selection, but are generally not suitable to predict actual corrosion rates. For this reason, the Electric Power Research Institute (EPRI) has cooperated with several gasifier

operators to obtain long-term corrosion rate data in various pilot and commercial-size gasification plants. Several materials have been exposed in various gasifiers for more than 50,000 h (Ref 4, 8–10). Individual tests have ranged from 2000 to 17,000 h, at temperatures ranging from 300 to 550 °C (572 to 1022 °F).

In general, the corrosion mechanisms found in laboratory tests are also found in service, such as type A corrosion under highly sulfidizing conditions at relatively low HCl levels and type B corrosion under less sulfidizing conditions, at somewhat higher HCl levels and high rates of corrosion due to scale spallation when chlorides are present in the deposits. Figure 8 shows an example of pitting and scale spallation of 310

stainless steel after 17,000 h exposure in a Texaco process gasification plant. The distribution of elements is useful in identifying corrosion products.

In the absence of scale spallation, stainless steels containing at least 20% Cr generally provide a satisfactory corrosion rate of about 0.1 mm/yr or less in the 300 to 400 °C (572 to 472 °F), the temperature range at which most heat exchangers in syngas coolers operate (Fig. 9). HR-160 (UNS N12160) shown in Fig. 9 is nominally 37Ni-29Co-28Cr-2.75Si. Corrosion mechanisms ranged from type B corrosion for the lower-chromium steels to type A corrosion for steels with a higher-chromium content such as 310 stainless steel.

When scale spallation due to chlorine migration to scale/metal interface occurs, corrosion rates increase considerably even at relatively low temperatures. Figure 10 shows the corrosion loss of the 310 stainless steel of Fig. 8, as a function of time. The rate is linear and is about 0.25 mm/yr. Here a molybdenum-containing alloy such as alloy 28 (27Cr-31Ni-3.5Mo-Cu, UNS N08028) is a better choice because it has a parabolic corrosion rate, with less than 0.25 mm loss after 17,000 h exposure. When the gasified fuel has very high chlorine levels, extremely high corrosion rates are possible. This is illustrated in Fig. 11, which gives the results of a 5500 h exposure test in a gasifier using a fuel containing 0.2 to 0.5% Cl. Here stainless steels have completely unacceptable corrosion rates, and molybdenum-containing alloys, preferably with a high nickel content such as alloy 625, are the only acceptable materials. It is interesting to note that alloy 625 is also the preferred alloy for waste-to-energy plants, where chlorine is the major corrodent under oxidizing conditions (Ref 11).

Material Selection. Field corrosion data from various gasifiers indicate that metal wastage rates experienced so far will not lead to catastrophically high corrosion rates. When sulfidation/oxidation is the only or major corrosion mechanism (type A corrosion), corrosion rates less than 0.1 mm/yr are generally experienced for steels with >20% Cr at temperatures below 400 °C (572 °F). Thus alloy 800 (20Cr-32Ni-Al-Ti), which is code approved for boiler service, would be an economical choice and is indeed frequently used. However, when the chlorine content of the fuel is somewhat higher and the syngas is less sulfidizing, type B corrosion can lead to highly increased corrosion rates. Under these conditions, alloy 800 and the weld filler metal FM82 (20Cr-72Ni-Nb, UNS W86082) are less suitable and alloys with a higher chromium content are needed. Type 310 stainless steel (Fe-25Cr-20Ni, UNS S31000) has adequate corrosion resistance, but is not approved for boiler service due to potential waterside corrosion problems. Alloy 28 is code approved and is also more resistant to chlorine-induced scale spallation (Ref 12). It is therefore the logical choice for application where type B corrosion or scale spallation is likely.

In isothermal laboratory corrosion tests, scale spallation under chlorine-rich deposits is observed only in tests combining exposure at high temperature, with shorter periods of exposure to humid air (downtime corrosion). Similar scale spallation is also frequently found in service, but it also occurs when exposure to aqueous corrosion conditions is infrequent, that is, when the plant operates continuously with only one or two shutdowns per year. Recently, corrosion tests were run under thermal gradients to study waterwall corrosion in boilers (Ref 13). It was found that chloride species in deposits can also move to the metal/scale interface and cause scale spallation when a thermal gradient is present, especially when the thermal gradient is steep

Fig. 9 Corrosion loss of stainless steels after 2000 h exposure in the Prenflo demonstration plant. Alloy 28 (UNS N08028), HR 160 (UNS N12160)

Fig. 10 Corrosion loss as a function of time of type 310 low-carbon stainless steel (UNS S31002) and alloy 28 (UNS N08028), during exposure in a syngas cooled at 390 to 420 °C (734 to 788 °F)

enough to cause melting of the chloride mixture. Thus, the authors now believe that aqueous corrosion during downtime is not the only cause of scale spallation, but that thermal gradients in deposits may be the main culprits, especially in commercial gasifiers, where downtime is infrequent.

Fuels used for present and future gasification plants can have dangerous chlorine levels. Refinery wastes, petroleum coke, and heavy oil bottoms have nominally low chlorine levels. However "phantom chlorides" have become a

problem in refineries (Ref 14). In one exposure test using heavy fuel oil, nominally free of chlorine, spallation due to chlorine corrosion was also experienced (Ref 14). The chlorine content of most coal is relatively low, 0.1% or less. However, the resulting HCl levels during gasification are much higher than in boilers, and chlorides are frequently found in heat-exchanger deposits, when gasifying coals with chlorine contents as low as 0.1%.

Biomass can also have surprisingly high chloride levels, although the chlorine level is

Fig. 11 Corrosion losses of stainless steels and nickel alloys from a coal-gasification plant, gasifying coal residues with 0.2 to 0.5% Cl. 304 (UNS S30400), 310Nb (UNS S31040), 800 (UNS N08800), 28 (UNS N08028), 625 (UNS N06625)

very source dependent. Thus, the chlorine content of the biomass should be an important selection criterion.

Conclusions on corrosion performance of CGCC are:

- Commercial-scale gasification power plants have operated trouble free for long periods of time and are commercially available.
- Corrosion losses due to high-temperature sulfidation alone are generally low enough to provide acceptable long-term service, especially when the chromium content of the alloy is 20% or higher.
- The presence of chloride-rich deposits can cause scale spallation, resulting in accelerated corrosion. When this occurs, common stainless steels have linear corrosion rates. Molybdenum-containing steels, which have

more adherent scales and exhibit parabolic corrosion rates, are preferred.

Corrosion in the Condensate-Feedwater System

Barry C. Syrett, Electric Power Research Institute
Otakar Jonas and Joyce M. Mancini, Jonas, Inc.

IN STEAM TURBINE ELECTRICAL POWER GENERATION PLANTS, turbine exhaust steam is condensed, and the condensate is reheated for return as feedwater to the boiler. Water from the condenser to the feedwater pump is called condensate, and from the pump to the boiler it is feedwater. This article addresses the major heat-transfer components in this part of the water-steam loop of a power plant: the condenser and the feedwater heater. These components are characterized by providing heat-transfer through metal walls between moving fluids. Both open-type feedwater heaters and condensers can function as deaerators. Deaerators may be separate units that also provide feedwater storage.

Corrosion of Condensers

Barry C. Syrett, Electric Power Research Institute
Otakar Jonas, Jonas, Inc.

The functions of a condenser include condensing turbine exhaust steam, generating a vacuum (which has a large effect on turbine efficiency), and deaerating the condensing steam. The condenser is a particularly critical component in a power plant, because condenser tube leaks and air inleakage affect many other components in the steam-water cycle (Ref 1–35). The root causes of many of the corrosion problems in fossil fuel boilers, nuclear steam generators, low-pressure steam turbines, and feedwater heaters have been traced to condensers that have leaked and allowed contamination of the steam condensate with raw cooling water and air. Most tube leaks are caused by corrosion, but some tube failures are purely mechanical, such as those caused by steam impingement (erosion), tube-to-tubesheet joint leaks, mechanical ruptures from foreign object impact, and tube vibration resulting in fretting wear and fatigue

(Ref 1–3). Purely mechanical failures are not discussed further.

Various methods are used to locate the sites of air and cooling water inleakage (Ref 34, 35), with helium leak detection being the best. Also, the presence of cooling water leaks can be detected by monitoring the condensate for sodium or cation conductivity (Ref 11).

Types of Condensers

Condensers may be cooled by water, air, or water spray.

Water-Cooled Condensers. A typical large utility condenser is a shell and tube heat exchanger comprising a carbon steel shell, two tubesheets, and thousands of straight tubes running between the tubesheets. It is usually located under the low-pressure (LP) turbine base, connected by a flexible joint, although smaller condensers may be connected to the LP turbine by a pipe. Heat is transferred from steam on the

outside of the condenser tubes (the shell side or steam side) to water on the inside (the tube side or water side). The cooling water passing through the tubes typically is pumped from a natural body of water, such as a river, lake, or ocean, or from various types of cooling towers. A schematic of a typical electric power plant condenser is shown in Fig. 1.

The lowest-pressure feedwater heaters may be located in the condenser neck. Condenser tubes are arranged to facilitate proper flow of wet steam through the array of tubes toward the air-removal region, from which the noncondensable gases are removed through a vent collector (Fig. 1) by external air ejectors or vacuum pumps (Ref 1–9). Makeup water for the main steam cycle is usually added into the condenser through a sparger (perforated pipe). The condensate, collected in the hotwell at the base of the condenser, is removed by one or more condensate pumps.

Air-cooled condensers are used where cooling water is not available or in environmentally

Fig. 1 Schematic of a typical condenser in an electric power plant. LP, low pressure

sensitive areas (Ref 2, 10). All components, including panels of finned tubes, are usually made of carbon steel. Here, the wet steam is on the inside of the tubes, and the coolant (air) is on the outside. The components are usually adequately protected against corrosion by normal steam and condensate chemistry (Ref 11). However, when the chemistry is out of control (low pH, high O_2), large quantities of iron corrosion products are generated, which can be transported into the feedwater and become harmful to boilers and turbines. Some designs of air-cooled condensers are subject to flow-accelerated corrosion (FAC) on the steam side, particularly at the transitions from headers to condenser tubes. During startups early in the life of the condenser, the condensate may be contaminated with organic preservatives, silica, and other impurities picked up from the tube walls. It is recommended that the condensate be filtered to minimize these effects.

The external surfaces of the finned tubes are prone to fouling from pollen, dust, insects, leaves, plastic bags, bird carcasses, and so on. Not only is the air flow affected but also the heat-transfer coefficient; the deterioration in performance increases unit operating costs.

To improve the heat-removal capacity of an air-cooled condenser under conditions of high ambient air temperature, operators sometimes spray water on the external surfaces of the heat-exchanger tubes to reduce the surface temperature. Unfortunately, depending on the hardness of the water used, this sometimes leads to scale formation on the tube fins and reduces the heat-transfer rate if the deposits are allowed to accumulate.

There have been a few air-cooled condensers made using aluminum tubes, but the experience with these has not been very good.

Other Types of Condensers. In smaller utility and industrial systems, the condenser can be part of a dry-wet cooling tower. In these designs, galvanized carbon steel condenser tubes are located at the bottom of the cooling tower and cooled on their outer surfaces by water spray. Typical problems include FAC on the steam side at the tube inlets and corrosion and erosion of the zinc plating on the tube outer surfaces.

Cooling Water Chemistry

The goal of cooling water chemistry control is to avoid formation of mineral scale, organic growth, and corrosion (Ref 28–32). However, the overall control is also significantly influenced by environmental regulations.

Cooling water chemistry control is governed by the chemical composition of the available cooling water sources, which range from low-conductivity, low-hardness freshwater to high-hardness freshwater to sea and brackish water and cooling tower water. All of these cooling waters can have various tendencies to corrode

condenser materials and to introduce organic fouling and mineral scaling.

The cooling water system treatment program actually chosen is often determined by the cost of the treatment relative to the costs of the corrosion, deposition, and scaling that would result in the absence of the treatment. Control of deposition, scaling, and microbiological growth in recirculating systems is achieved through the addition of chemicals that adjust the pH and alkalinity of the cooling water, inhibit scale growth, act as dispersants or complexing agents, or inhibit microbiological growth.

In once-through cooling water systems, the same approach cannot be taken, due to cost and environmental regulations. The water chemistry typically is not controlled, except for filtration of the water and, quite frequently, some type of biofouling control. In both once-through and recirculating systems, the addition of chlorine or nonoxidizing biocides is common.

Corrosion Mechanisms

Data collected by the North American Electric Reliability Council from 1476 fossil units in 168 utilities between 1996 and 2000 show that condensers were responsible for 25,955 forced and scheduled outages and deratings, costing the utilities 53,869 GWh (Ref 36). Table 1 lists several of the components that were responsible for the failures as well as the associated losses. The component failure statistics shown in Table 1 do not specify the damage mechanism or cause of the outage, but the main component problems, such as those in tubes, tubesheets, expansion joints, vacuum pumps, or air-inleakage-related problems, are frequently caused by corrosion or erosion. The leaks in these components allow corrosive impurity ingress, which promotes corrosion in other steam cycle components.

Corrosion mechanisms active in condensers and giving rise to known service problems are summarized in Table 2 (Ref 1–3, 11–25, 37). Information on tubesheet materials requires special explanation. Because tubesheets are very

thick (>25 mm, or >1 in.), corrosion rates can be 15 to 50 times higher than in condenser tubes and still be considered acceptable in most cases. Furthermore, even if corrosion is a serious problem in a tubesheet, inspections are usually scheduled frequently enough, and the tubesheet is thick enough, that suitable repairs can be made or corrosion protection procedures can be instituted long before the tubesheet is penetrated. Thus, although Table 2 indicates that copper alloy tubesheets have suffered significant (often severe) galvanic corrosion under certain conditions, leakage of cooling water through the tubesheet from the water side to the steam side has rarely occurred. Each of the corrosion mechanisms found in condensers is reviewed as follows.

Erosion-Corrosion (Water Side). Erosion-corrosion is a relatively common water-side phenomenon that is only a problem in copper alloy condenser tubes (Ref 2, 3, 5, 14, 22). It occurs in areas where the turbulence intensity at the metal surface is high enough to cause mechanical or electrochemical disruption of the protective oxide film. In these turbulent regions, pitlike scalloped features develop. Turbulence increases as the flow velocity increases, and it is greatly influenced by geometry. For example, turbulence intensity is much higher at tube inlets than it is several feet down the tubes, so, if erosion-corrosion is a problem, it is commonly found in the first 25 cm (10 in.) of copper alloy tubes. Tube inserts and tube end coatings have been used to circumvent this problem. A tube insert is a tightly fitting internal sleeve, typically 150 to 300 mm (6 to 12 in.) long, made from an erosion-corrosion-resistant material that shields the susceptible tube ends. However, unless there is a smooth transition (feathered edge) between the end of the insert or coating and the tube, the transition can create turbulent conditions and promote erosion-corrosion further down the tube (Fig. 2). Electric Power Research Institute (EPRI)-funded experiments have demonstrated that inlet-end erosion-corrosion can also be prevented by installing a cathodic protection system in the water box region (Ref 38). Reducing the cooling water flow velocity and distributing flow

uniformly across the tubesheet also reduce erosion-corrosion. Some suggested maximum cooling water flow velocities are shown in Table 3.

Water box and water intake design can be the source of inlet end erosion-corrosion problems. The preferred arrangement is a hemispherical inlet chamber with the inlet pipe centered in the hemispherical head. This arrangement results in reasonably uniform flow to all tubes and minimizes tube inlet end erosion-corrosion. Other arrangements (inlet perpendicular to the water box, flat rather than hemispherical water boxes, and other variations due to space limitations) often lead to turbulence and erosion-corrosion at the inlet end of nonferrous-tubed condensers.

Erosion-corrosion may also occur when marine life or debris in a tube creates a partial blockage, resulting in locally high velocities through the restricted opening. In these cases, the best solution is to keep the tubes clean, using one or more of the following methods:

- Install or improve intake screens
- Install on-line sponge ball cleaning
- Periodically reverse flow (backwash)
- Manually clean with brushes, balls, scrapers, and so on (off line)
- Prevent biofouling by chlorination or thermal shock
- Decrease intake screen openings to one-half the tube diameter

Alternatively, some copper alloys—such as aluminum brass in saline waters—benefit from periodic dosing of the water with ferrous ions (Fe^{2+}), which are usually added as ferrous sul-

fate (FeSO_4) solution. The Fe^{2+} ions deposit as a protective lepidocrocite [$\text{FeO}(\text{OH})$] layer on the copper alloy surface.

Sulfide Attack (Water Side). This form of attack affects only copper alloys and occurs when the cooling water, most often brackish water or seawater, is polluted with sulfides, polysulfides, or elemental sulfur (Ref 2, 3, 5, 12, 39). As little as 10 mg/m^3 (10 ppb) of sulfide in the cooling water can have a detrimental effect, and concentrations far greater than this are often measured in polluted harbors and estuaries. Sulfide attack manifests itself in many ways. It can greatly increase general corrosion rates, and it can induce or accelerate dealloying, pitting, erosion-corrosion, intergranular attack, and galvanic corrosion. Penetration rates in polluted waters can be extraordinarily high, sometimes as high as 20 mm/yr (790 mils/yr). No copper alloy is resistant to sulfide attack, and the relative performance of copper alloys in polluted or brackish waters seems to depend on the precise environmental conditions (Ref 14, 20–22, 38–43).

If the incoming water contains sulfide and there is no obvious method of eliminating the source, one possible method of reducing or preventing the problem is to dose the water periodically or continuously with FeSO_4 or some other source of Fe^{2+} ions (Ref 44). If this approach is used, compliance with environmental discharge requirements for ferrous ions should be checked. However, sulfide attack can also occur in condensers cooled with nominally unpolluted water if marine organisms trapped within the condenser during downtime are allowed to die and putrefy to produce sulfides.

This can be prevented by maintaining circulation of the cooling water during downtime or, for longer outages, by draining the tubes and drying them with warm, dehumidified air. In addition, sulfate-reducing bacteria can produce sulfides under debris and deposits where the oxygen content is low. Thus, the risk of sulfide attack is greatly reduced if the copper alloy tubes are regularly cleaned (Ref 44).

Dealloying (Water Side). Dealloying is the selective corrosion of one or more components of a solid-solution alloy and is also known as parting. The more active (reactive) components of the alloy corrode preferentially, leaving behind a surface layer that is rich in the more noble alloying elements. Dealloying has been reported in condenser tubes, tubesheets, and water boxes (Ref 2, 3, 5, 15). Dezincification may occur in brass tubes and tubesheets, denickelification in copper-nickel alloy tubes, dealuminification in aluminum bronze tubesheets, and graphitic corrosion in cast iron water boxes.

Dealloying is rarely the cause of condenser tube failures, but when it does occur, it is generally found beneath deposits and at hot spots and is promoted by stagnant conditions. This results in plug-type dealloying. A much less localized form of dealloying, termed layer-type dealloying, is rare in tubes but has occasionally occurred in brass tubesheets, particularly in conjunction with galvanic corrosion induced by titanium or stainless steel condenser tubes (Ref 19).

The occurrence of dealloying in copper-base alloys is critically dependent on the major and minor alloying elements present. Copper-zinc

Table 2 Corrosion mechanisms that have caused problems in power plant condensers under certain conditions

alloys are highly susceptible to attack, while copper-nickel alloys are generally considered to be more resistant. In copper-zinc alloys, dealloying (dezincification) is inhibited by the addition of arsenic, antimony, and phosphorus. Dealloying attack is frequently associated with improper heat treatment of the multiphase alloys that are used for tubesheets. However, heat treatment has little effect on dealloying of single-phase materials such as admiralty brass, 90Cu-10Ni, and 70Cu-30Ni.

Graphitic corrosion, which occurs occasionally in cast iron condenser water boxes, has also been labeled a form of dealloying, even though, in this case, selective corrosion does not occur in a solid-solution alloy. Graphitic corrosion results from the deterioration of gray cast iron in which the metallic constituents are selectively leached or converted to corrosion products, leaving behind a surface profile that is largely unchanged but is composed of a weak, porous mass of graphite.

A cathodic protection system installed in the water box will control both galvanic corrosion and dealloying. Where dealloying problems have been encountered in condenser tubes, frequent tube cleaning and minimizing the occurrence of stagnant conditions (such as wet lay-up) can reduce the rate of attack. Alternatively, tube materials that are resistant to dealloying, such as titanium, stainless steel, and inhibited copper-base alloys, can replace the dealloying-sensitive alloys.

Crevice Corrosion and Pitting (Water Side). Brass and austenitic stainless steel condenser tubes are known to have failed by cooling-water-side pitting and crevice corrosion (Ref 2, 3, 5, 14, 16–18). There is limited evidence that copper alloys have adequate resistance to these forms of corrosion if the cooling water is completely free of sulfide. Certainly, the susceptibility seems to be greatly increased when sulfide is present.

Pitting and crevice corrosion of stainless steels are more dependent on the chloride content of the cooling water than on the sulfide content, although laboratory data have demonstrated that the detrimental effects of chloride are accentuated in the presence of sulfide. Some alloys, such as AISI type 304 and 316 stainless steels, which generally perform well in freshwaters or slightly brackish waters, suffer rapid pitting and crevice corrosion in seawater (Fig. 3). Stagnant seawater left in austenitic stainless steel tubes can perforate the tubes in a few weeks. The more highly alloyed stainless steels, including AL6X (UNS N08366), AL29-4C (Fe-29Cr-4Mo-0.35Si-0.02C-0.02N-0.24Ti), and Sea-cure (Fe-27.5Cr-3.4Mo-1.7Ni-0.4Mn-0.4Si-0.02C-0.5Ti+ Nb), generally perform well even in seawater. However, a few failures have been reported for AL6X and for some of the early heats of Sea-cure.

The initiation of pitting in stainless steels may be stimulated by the dissolution of inclusions at the metal surface. Manganese sulfide (MnS) inclusions, for instance, are formed in stainless

steels when the manganese content approaches 2%. These inclusions are soluble in water and, depending on the size of the inclusion, could result in the formation of a corrosion cell or just dissolve and leave a pitlike hole.

On the cooling water side, crevice corrosion occurs where surfaces are in close proximity and are not boldly exposed to the water environment, such as at a poorly formed tube-to-tubesheet joint. Imperfect construction methods that result in tubesheet hole ovality, tube-to-tubesheet joint underrolling, and inadequate flaring have been identified as potentially leading to crevices that can stimulate crevice corrosion.

Tube cleanliness is a critical issue, because debris, biofilms, and deposits promote the formation of concentration cells (the precursor to crevice corrosion) and the production of sulfides. The tube-cleaning techniques summarized earlier in this section are therefore equally useful in preventing crevice corrosion and pitting in copper alloys and stainless steels. Other solutions include:

- Eliminating tube-to-tubesheet crevices by seal welding the joints
- Applying cathodic protection or protective coatings

Fig. 3 Example of pitting in type 316 stainless steel in seawater service

- Avoiding lay-up periods with stagnant water left in the condenser tubes, particularly sea and brackish water in austenitic stainless steel tubes
- Flushing during outages
- Chemically treating cooling water

Galvanic Corrosion (Water Side). Galvanic corrosion is corrosion associated with the current resulting from the electrical coupling of dissimilar metals (electrodes) in an electrolyte. Galvanic corrosion is not a problem in low-conductivity waters, such as those normally found on the steam side of condensers. However, it can be a water-side problem in condensers cooled with seawater or with medium- or high-conductivity fresh and brackish waters.

In seawater, tube materials, such as copper-nickel alloys, stainless steels, and titanium, are more noble than tubesheet materials, such as Muntz metal and aluminum bronze. Consequently, the tubesheet may suffer galvanic attack when fitted with these more noble tubes (Fig. 4) (Ref 2, 3, 19). Laboratory tests have demonstrated that the rate of galvanic corrosion of a Muntz metal tubesheet fitted with titanium or stainless steel tubes can exceed 5 mm/yr (200 mils/yr) in seawater (Table 4) (Ref 19). Similarly, if stainless steel inserts are installed in copper alloy tubes to prevent inlet-end

erosion-corrosion, rapid galvanic corrosion can be promoted in the tube close to the insert/tube interface.

Other galvanic couples can exist in a condenser. In each case, the recommended method of alleviating the problem is to install a cathodic protection system in the water box. Electrical current requirements can be reduced by coating the tubesheet and water box with a nonconducting material.

Environmental Cracking (Water Side and Steam Side). Stress-corrosion cracking (SCC) and hydrogen embrittlement cracking are forms of environmental cracking that can affect condenser tubes (Ref 2, 3, 5, 14, 15). Hydrogen embrittlement cracking was identified as a problem on the water side of ferritic stainless steel tubes in a couple of condensers fitted with cathodic protection systems. It is believed that hydrogen was generated on the surface of the tubes by the passage of too high a cathodic protection current and that this hydrogen promoted slow crack growth and failures at the ends of the tubes. The tube ends were particularly susceptible to hydrogen embrittlement cracking, because roller expansion during fabrication introduced higher-than-normal residual stresses in these zones.

Entry of hydrogen into cathodically protected titanium tubes is also possible if too high a cathodic protection current is delivered. In such cases, the absorbed hydrogen can react with the metal to form a brittle titanium hydride phase, which could conceivably crack and lead to premature failure. However, so far, no titanium condenser tube failures have been reported. One electric power producer that grossly overprotected the water box region of a titanium-tubed condenser discovered that the ends of the tubes were severely hydrided, but even here the affected tubes did not leak.

Apart from the rather unusual failures in ferritic stainless steels, environmental cracking is only a problem in copper alloys, specifically the brasses. Here, SCC (not hydrogen embrittlement cracking) is the mechanism of failure. Most SCC failures initiate on the steam side of the tubes when the steam condensate contains high concentrations of NH_3 and oxygen (Ref 11). The NH_3 is derived from the chemicals added for boiler feedwater chemistry control, and oxygen originates from air that leaks into the system through imperfectly maintained turbine glands, expansion joints, valve packing glands, and so on. The NH_3 and oxygen concentrations are particularly high in the air-removal section, and it is here that SCC occurs most frequently. Stainless steel or copper-nickel is often used in this section, rather than brass, to avoid SCC due to NH_3 .

Steam-side SCC can be controlled by ensuring that the condensate on the tubes has a low oxygen concentration. The maintenance of an airtight system requires continuing attention to all seals, glands, and joints that are subjected to internal pressures less than atmospheric during start-up, normal operation, or shutdown. Helium tracer

and similar techniques allow leaks to be detected with moderate ease.

Water-side SCC of brasses has occurred less frequently than steam-side attack, and in most cases, the chemicals responsible for the failure were not positively identified. However, NH_3 and its derivatives (nitrates and nitrites) are often suspected of promoting SCC. Possible sources of these chemicals are farm fertilizers (runoff) and decaying organisms in polluted water. Water-side failures frequently initiate beneath surface deposits, probably because the deleterious species can concentrate beneath the deposit to levels that favor SCC. Thus, once again, tube cleanliness is important, and cleaning techniques can be used to minimize water-side SCC.

No matter which side of the tube is susceptible to environmental cracking, the cracking can be controlled by reducing or eliminating residual tensile stresses. Roller expansion of the tubes during installation will always introduce some residual stresses, but care should be taken to avoid expansion beyond the back of the tubesheet, which can lead to particularly high residual stresses. In addition, fully stress-relieved tubes should be used, and during installation, they should not be bent or mechanically abused.

In addition to the condenser tubes, the condenser shell, support structure, makeup inlet sparger, and drain baffles, all typically made of welded carbon steel, can also be subject to environmental cracking. A combination of residual welding stresses, vibration caused by steam flow and flashing of various drains, and wet steam and condensate can lead to SCC and corrosion fatigue. Improvement of weld quality, control of vibration by design, and avoidance of critical transonic flow in drains will help to prevent these problems.

Condensate Corrosion (Steam Side). Condensate corrosion may occur on the steam side of copper alloy condenser tubes either in a relatively uniform manner (i.e., general corrosion) or preferentially at certain locations. The latter form of attack is known as ammonia attack, ammonia grooving, or condensate grooving. Both types of condensate corrosion occur in locations where the steam condensate contains high levels of ammonia, carbonate, and dissolved oxygen (Fig. 5) (Ref 20–23). Consequently, condensate corrosion, like SCC, is most prevalent in the air-removal section. Ammonia is a component of the all-volatile treatment of feedwater, and carbonate (carbon dioxide) and oxygen come from air that leaks into the condenser. Other sources of CO_2 are decomposed organic impurities and organic water treatment chemicals and aerated makeup water.

General Corrosion. This type of corrosion may occur during operation or during shutdown periods. General corrosion during operation is reduced by controlling air leakage or by ensuring—through good design—that air is removed effectively from the condenser. General corrosion during extended shutdown periods can be minimized by eliminating moisture from the steam side by flowing either filtered dehumidified air or nitrogen through the system. Condensers may also be retrofitted with stainless steel or titanium tubes to avoid condensate corrosion and the subsequent transport of copper corrosion products. Copper can play a critical role in the corrosion of other components in the main steam cycle.

Ammonia Grooving. This form of condensate corrosion is localized, because the corrosive environment is localized (Ref 2, 5, 14, 23) (Fig. 6). For example, the slight tilt routinely

Fig. 5 Corrosion rates of copper alloys in aerated ammonia drip solutions. Source: Ref 26

given to condenser tubes may promote flow of some of the steam condensate toward one side of a tube support plate. There, the flow from a large number of tubes can collect and run down the plate surface. Such localized flow can create deep circumferential corrosion grooves in the tubes immediately next to the support plate (Fig. 6b) if the condensate contains high levels of ammonia and oxygen. Ammonia grooving can be controlled by reducing the oxygen concentration in the condensate, as discussed previously for steam-side SCC, or by selecting more resistant alloys, such as copper-nickel alloys, or completely resistant alloys, such as stainless steels and titanium.

Biofouling Control

Minimizing biofouling on the cooling water side of a condenser will reduce corrosion (Ref 24–26). In some instances, microbial activity does nothing more than create localized geometric conditions, for example, a crevice beneath a microbial growth, that stimulate crevice corrosion. In other circumstances, microbes produce metabolites, such as organic or mineral acids, ammonia, or hydrogen sulfide, that are corrosive to structural materials. A few microbes can concentrate chlorides and other halides, which can result in severe, localized corrosion of passive materials, such as stainless steels and nickel alloys.

Furthermore, detached biofouling organisms can clog or partially plug tubes, possibly causing accelerated attack immediately downstream of the entrapped organisms. During shutdowns or in stagnant water conditions, the organisms may die and putrefy, producing trace quantities of sulfide and nitrogen compounds that may cause localized attack or cracking of some alloys.

The two most common methods used to control biological fouling in surface condensers are chlorination and thermal shock. Chlorination is usually achieved in one of three ways: injection of chlorine gas through an appropriate regulator, injection of sodium hypochlorite, or the generation of chlorine in situ using a dual-electrode generator. Typically, the cooling water is dosed with chlorine sufficient to produce a small residual amount of free chlorine (~0.5 ppm). The frequency, duration, and amount of chlorine

dosage vary from plant to plant and can be quite dependent on the time of year.

To a lesser degree, thermal shock is employed as a method for controlling biological fouling. Recirculating the cooling water flow through the condenser so that the temperature increases to 49 °C (120 °F) will kill off most of the organisms. Thermal shock is effective against larger organisms that have a higher tolerance for chemical biocides.

Other Problems

Other problems include:

- Erosion and erosion-corrosion of the carbon steel condenser shell and the structural elements that generate iron oxides, which are transported into the steam cycle
- General corrosion and pitting corrosion of condenser shell bottoms that sit on a concrete slab
- Air ejector erosion
- Corrosion fatigue of carbon steel baffle and sparger welds

Corrosion Prevention

Many corrosion mechanisms active in condensers can be prevented if only two maintenance procedures are followed. First, if air is eliminated from the steam, condensate corrosion and SCC of copper alloy tubes can be minimized. Second, if condenser tubes are kept clean and free of deposits, debris, and biofouling on the water side, sulfide attack, dealloying, erosion-corrosion, crevice corrosion, pitting, and SCC can be prevented or minimized.

Corrosion of Deaerators

Otakar Jonas and Joyce M. Mancini, Jonas, Inc.

Deaerators have been used for more than 50 years in fossil utilities and industrial cycles to

remove dissolved gases (mostly oxygen, carbon dioxide, and nitrogen) from feedwater through mechanical deaeration (Fig. 7). By removing dissolved gases from the droplets of feedwater formed in spray nozzles and trays, deaerators help to reduce corrosion in the preboiler system and the boiler. Deaerators also provide water storage capacity to supply boiler feed pumps and allow chemical oxygen scavengers to have a residence time at appropriate elevated temperatures. In addition, the hydrostatic head provides the proper flow conditions and pressure for the boiler feed pump suction. The design, material of construction, and environment affect the corrosion of deaerators (Ref 45–72).

Deaerator Designs

There are many deaerator design configurations, both horizontal and vertical, with different types of internals where feedwater and steam interact. Typical designs incorporate spray, tray, or combination spray/tray deaerating/heating sections. In electric utility deaerators, turbine extraction steam is used. The deaerator is located between the low-pressure and high-pressure feedwater heaters. In industrial steam cycles, main or hot reheat steam is used for deaeration. In combined cycle units, low-pressure boiler steam is often used for deaeration, and a deaerator may be combined with the low-pressure drum.

Spray Deaerators. Feedwater sprays into a steam-filled space where it is heated and scrubbed to release gas. As fresh steam enters the unit, it passes through the sprayed water, agitating the water a second time and liberating most of the remaining volatile impurities.

Tray Deaerators. Feedwater is directed onto a series of cascading trays. Water falls from tray to tray by overflowing or passing through small holes. Steam, which engulfs the trays, heats and deaerates water as it falls.

Combination Heaters. Feedwater first sprays into a steam-filled space, then rains down on a series of trays through which it passes for further agitation and scrubbing.

Both spray- and tray-type deaerators should be able to remove oxygen to less than 7 ppb, and the deaeration efficiency should be good even at low loads. Incomplete deaeration occurs when trays

are not properly aligned, spray nozzles plug or fail, or when the deaerator steam temperature or flow are low.

Corrosion Problems and Solutions

Stress-corrosion cracking (SCC) and corrosion fatigue (CF) of the deaerator storage tank and deaerating vessel welds is an industrywide (utility and industrial steam plant), generic problem. It has led to catastrophic failures and fatalities (Ref 45, 50, 51, 54, 55, 58–61) and is still a major maintenance and inspection burden, with cracking in more than 30% of utility and industrial plant deaerators. NACE Task Group T-7-H7 on Deaerator Cracking identified seven catastrophic failures of deaerator storage and hot water tanks due to stress-corrosion cracking and corrosion fatigue (Ref 52). Similar cracking occurs in blowdown flash tanks and other welded carbon steel pressure vessels and piping. Other deaerator damage mechanisms include general

corrosion, pitting, and flow-accelerated corrosion (Table 5).

Weld Cracking (Stress-Corrosion and Corrosion Fatigue). Deaerator cracking has been predominantly found in the welds of the vessel shell (Fig. 7) in either the heat-affected zones (HAZs) or in the welds (Ref 45–49, 53). Weld cracking most frequently forms perpendicular to the welds, but cracking parallel to the weld, especially at the toe, is also common (Fig. 8). In many vessels, the most serious cracking has been found in the head-to-shell circumferential weld. Welds of various internal attachments also crack.

In a paper mill, cracking at a head-to-shell circumferential weld resulted in a catastrophic failure and fatalities. The break before leak occurred during normal operation after the slow-growing corrosion crack reached approximately 50% of the wall thickness over approximately 280° of the circumference. At that point, the stress-intensity factor reached the material fracture toughness value and the head separated. The

hot pressurized water flashed into steam, propelling the deaerator through the mill.

Cracks perpendicular to the welds are believed to be SCC cracks, and cracks parallel with the welds, CF cracks. There can be an interaction of both cracking mechanisms. Crack initiation has often been attributed to pitting. Stress-induced pitting (Ref 69) can also be an initiation mechanism.

There is a good correlation between the crack propagation rate and the time in service (Fig. 9a), which may indicate that the older deaerators were fabricated with lower residual welding stresses. Increases in welding productivity by faster, higher-energy input welding can produce higher residual stresses. There has been little correlation found between cracking rate and either operating pressure or the design-to-operation pressure ratio (Fig. 9b, c) (Ref 50, 54).

A survey of deaerators inspected by the wet fluorescent magnetic particle method indicated that the presence of “water hammer” (caused by water entering a steam line or steam-filled space) is a possible cause of deaerator cracking (Ref 50, 53). Of the four deaerators reported to have water hammer but no cracks, three were in service less than 4 years at the time of inspection. This limited survey could not draw any conclusions about the effect of basic structural design, materials of construction, deaerator type, operating pressure, operating history, or water chemistry on cracking.

Internal surfaces of the vessel where attachments are welded to the exterior surfaces have also shown cracking. Cracking is perpendicular to the surface and primarily in a straight line, although some have shown limited branching.

Causes and Prevention of Weld Cracking. There are no confirmed root causes of deaerator weld cracking, and there has not been any comprehensive research to determine root causes and verify corrective measures. This is in addition to the general ignorance about stress-corrosion cracking and corrosion fatigue mechanisms.

The most likely root causes of deaerator weld cracking (based on hundreds of cases) are listed in Table 6, along with possible preventive measures.

Corrosion cracks can initiate at welds because of high residual tensile stresses, weld defects,

increased corrosion susceptibility of weld and HAZ, and stress concentrations occurring in these locations. However, both stress-relieved and nonrelieved welds experience the cracking, and, in a few cases, residual stresses after stress relief were still close to yield strength. In many cases, the cracking mechanism appears to be low-cycle corrosion fatigue (Ref 49), and it occurs over a long period. Applied stresses contributing to the cracking are likely caused by water piston (Ref 45, 50, 54, 64), water hammer, and by internal pressurization.

Water piston is an unstable water surface waviness (Kelvin-Helmholtz instability) occurring in partially filled horizontal liquid storage vessels, such as in horizontal deaerator storage tanks (Ref 45, 50, 54, 64). The inflow of water can cause the standing waves to close the whole cross section (a piston), and when there is a

pressure differential along the vessel, the piston is propelled toward the end of the vessel. This can occur repeatedly, leading to a generation of alternating stresses and to corrosion fatigue of the head-to-shell welds. It is recommended that designers perform an evaluation for water piston conditions (Ref 45, 50, 54, 64).

Weld Inspection. It is recommended to periodically inspect deaerator welds, to determine crack depth, crack propagation rate under corrosion fatigue, and stress-corrosion conditions, and to calculate residual life and a safe inspection interval.

For new deaerators, stress relief of welds and radiographic weld inspection are recommended but not mandated in the ASME Boiler Pressure Vessel Code.

Deaerators should be inspected during commissioning of new units and about every 5 years

thereafter, or when operation has changed (e.g., from base load to cycling operation). Deaerators should be monitored for water piston, water hammer, and other unsteady phenomena that can generate fatigue stresses; operation should be adjusted to eliminate such conditions. The NACE Recommended Practice for Prevention, Detection, and Correction of Deaerator Cracking (Ref 46) provides guidance on proper inspection techniques. It recommends wet fluorescent magnetic particle inspection after light grinding of the welds inside the vessel. Acoustic emission and ultrasonic inspection methods have also been used.

An engineering evaluation of inspection results should be done with considerations of corrosion fatigue and stress-corrosion crack propagation rates and service experience. The remaining life from the time of inspection to a leak or break should be calculated and repair or next, nondestructive test (NDT) interval recommended (Ref 50). The most important NDT information is crack depth. A block diagram of the life-evaluation procedure is shown in Fig. 10. In this procedure, data on operating history, stress analysis, and results of NDT are used to determine the maximum stress intensity for SCC and CF crack growth calculations in which the material properties for specific water chemistry and operating temperature are used. The time for SCC and CF cracks to lead to a leak or final fracture are calculated (residual life), and the NDT interval is determined, usually as 50% of the residual life.

Preferential Corrosion in the HAZ. During welding, the base metal is rapidly heated and cooled with filler material being added to the joint. Temperatures experienced in the HAZ during welding range from ambient at a distance away from the weld to the melting point. As a result, the microstructure across the HAZ and weld metal will vary from that of the base metal.

Although not widely recognized, the HAZ can be subject to preferential corrosion (Fig. 11) (Ref 63). The phenomenon has been observed in a wide range of environments with the common links being an elevated conductivity and pH values normally ranging from below 7 to about 8.

Fig. 8 Cracks associated with carbon steel deaerator welds, (a) transverse in the weld and (b) longitudinal. (c) Closeup of crack tip in (b). Courtesy of Jonas, Inc.

Fig. 9 Deaerator storage tank weld cracking: crack depth as a percentage of wall thickness per year versus (a) time in service, (b) operating pressure, and (c) operating/design pressure ratio. Source: Ref 50

The reasons for localized weld attack are not fully known. There is a microstructural dependence, and there are differences in weld and base metal composition and strength. Corrosion has been shown to be more severe when the material composition and welding are such that hardened structures are formed (Ref 63). It is known that hardened steel may corrode more rapidly under acidic conditions than tempered material. On this basis, water treatments ensuring alkaline conditions should be less likely to induce HAZ corrosion. However, even at $\text{pH} = 8$, hydrogen ion reduction accounts for approximately 20% of the total corrosion (Ref 63). Therefore, a pH well above 8 would be required to completely suppress the pH effect.

Flow-accelerated corrosion (FAC) can be found in selected sections of deaerators and piping where there is high velocity or turbulent flow, typically at the outlet of the deaerating vessel and other piping connections (Ref 70–72). In vertical deaerators, where there is tangential flow between the deaerating and storage section,

FAC is found more frequently than in horizontal deaerators. Because the water in the deaerator is at saturation conditions, any changes in the static pressure can also lead to evolution of steam and gas bubbles and cavitation. Erosion and FAC of the impingement baffles near the steam inlet connection has been a problem in some spray-type deaerators.

The parameters that govern FAC include: flow velocity and turbulence, component geometry, temperature, feedwater chemistry (pH, oxygen, and oxygen scavenger), and material composition (chromium, copper, molybdenum) (Ref 70–72). Flow-accelerated corrosion is well understood, and inspection methods and engineering solutions have been developed. Besides the effect on integrity, the main effect of FAC is the generation of iron oxides and their deposition in the boiler and turbine (via attemperating sprays).

Deaerator and associated piping design should be evaluated for susceptibility to FAC and cavitation using commercially available

software (Ref 72). The areas identified as susceptible to FAC should be inspected visually and for thinning by ultrasonic thickness testing. Maintaining feedwater pH above 9.5 with residual concentration of oxygen and minimizing the concentration of oxygen scavenger can significantly reduce FAC. In once-through and drum boiler cycles with condensate polishing and good feedwater, FAC can be reduced by oxygenated feedwater treatment. Components with a high thinning rate identified by wall thickness measurements should be replaced with alloy steel components.

General Corrosion. There is often some general corrosion of deaerators, particularly during unprotected layup with aerated water left in the storage tank or by humid air. The main effect of general corrosion of deaerators is an increase in the iron concentration in feedwater leading to scale formation in the boiler. In cases of poor feedwater chemistry with high cation conductivity, low pH, and high oxygen concentration, there can be severe general corrosion. General corrosion can be controlled to acceptable levels by maintaining feedwater chemistry within recommended guidelines (Ref 66, 67) and using proper layup procedures (Ref 67, 68).

Pitting. A deaerator cracking survey (Ref 53) found that 30% of deaerators with pits also had cracks in the weld areas. However, pitting in deaerators is not a major problem. It sometimes occurs when feedwater contains chloride, oxygen, CO_2 , and other corrosive impurities. Pitting can be active during both operation and layup (Ref 45, 46, 50, 54). Metal oxide and mineral scale, which is often thicker around welds, can concentrate impurities and accelerate pitting. The main effect of pits in the weld area is the initiation of cracking.

Pitting in deaerators can be avoided by maintaining good feedwater chemistry and protection during layup (Ref 67, 68). To minimize pitting and its effect on crack initiation, the deaerator scale and deposits should be removed during inspections and pits in weld and other areas susceptible to cracking should be removed by grinding; however, the minimum allowable wall thickness should be preserved.

Tray Enclosure Box in Vertical Deaerators. General corrosion, pitting, and SCC resulting in massive cracking of 304L stainless

Table 6 Probable root causes and preventive measures for deaerator weld cracking

Probable root cause	Prevention
Residual welding stresses	Qualified welding procedure, stress relief, control of fatigue stresses (water piston and water hammer)
Generic problem of SCC and CF of carbon steel welds, even in high-purity water	Reduction of residual stresses and control of transient stresses, water piston, and water hammer
Rapid load and pressure changes producing condensation and evaporation (flashing) shocks	Adjust operating procedures, test during commissioning
Water piston (Ref 45, 50, 54, 64) and water hammer	Evaluate deaerator design, adjust operation, test during commissioning
Weld defects	Qualified welding process and welders, radiography of welds
Water chemistry (a secondary effect)	Follow recommended guidelines

steel enclosure boxes have been experienced in several vertical deaerators. The corrosive environment was not positively identified, but there is a suspicion of the presence of organic acids and elevated oxygen.

Spray Valve Spring SCC and CF. Stress-corrosion cracking and CF of spray valve springs, usually made of higher-strength stainless steels, have been experienced in numerous deaerators. Cracks are detected during routine inspections and replaced.

Corrosion of Feedwater Heaters

Otakar Jonas and Joyce M. Mancini, Jonas, Inc.

Feedwater heaters (FWH) increase overall cycle efficiency by heating feedwater using low-pressure (LP) and high-pressure (HP) steam from the turbines. Design, materials of construction, and environment affect the corrosion of feedwater heaters (Ref 73–96).

Types of Feedwater Heaters

Channel Feedwater Heaters. This design consists of a flat tubesheet that holds the straight or U-shaped tubes in a shell (Ref 80). Feedwater heaters are typically designed with condensing and subcooling zones (two-zone) or with desuperheating, condensing, and subcooling zones (three-zone). A typical example of a three-zone heater is shown in Fig. 12.

Header Feedwater Heaters. This design is a header-type construction, patterned after boiler header applications (Ref 74, 76, 81, 82). The feedwater inlet and outlet headers have tubes and nipples attached to each header. Between the headers, the tubes are in a W-shape in the heater. The header-type heaters are much larger, more expensive, and more difficult to maintain than the tubesheet-type heaters. The main advantage of the header-type heaters is better thermal design for cyclic service.

Materials

The frequency of failures and failure modes for feedwater heaters vary considerably from one class of materials to another (Ref 73, 76, 77, 79, 80, 82, 83, 88–92). All feedwater heater parts (e.g., shell, head, internals, and piping) except the tubes are carbon steel. Commonly used FWH tube materials are admiralty brass and other brasses, copper-nickel alloys, Monel, carbon steel, and stainless steels (Table 7).

Admiralty and Other Brasses. The major corrosion problems associated with admiralty and other brasses are general corrosion, flow-accelerated corrosion (FAC), and stress-corrosion cracking (SCC) (Ref 79, 88–92). In most instances, general corrosion of these tubes is not associated with premature tube failure, but the copper released in the system has been implicated in corrosion failures of other power-plant components in the steam/water cycle.

Copper-Nickel Alloys. The major corrosion problems associated with copper-nickel alloy tubes are general corrosion (copper and nickel release), exfoliation, and stress-corrosion cracking (Ref 79, 83, 88–92). Exfoliation tends to be most severe in units that operate in peaking service, presumably because O_2 levels are higher; the tubes most affected are those made of 70Cu-30Ni, while 90Cu-10Ni are reported to be least attacked. In this type of service, SCC failures have been reported in 90Cu-10Ni and 80Cu-20Ni tubes. Most frequently, these failures have occurred on the steam side in locations where high residual stresses were present.

Monel Alloy 400. Few failures of Monel alloy 400 tubes have been reported in feedwater

heater applications (Ref 88, 92). Because of the excellent corrosion resistance and high allowable stresses of Monel alloy 400, it is most frequently used in high-pressure feedwater heaters where its high cost can be justified. In general, the environments found in HP FWHs are more aggressive than those found in the lower-pressure units. Those Monel failures that have occurred generally have been attributed to secondary causes such as tube-vibration-induced wear, mechanical damage during installation, and steam impingement as a result of improper FWH design. As is the case with copper-base alloys, corrosion product release is of concern with Monel. A few SCC failures also have been reported. In most cases, these have been intergranular in nature and have been associated with high residual stresses. Initiation of SCC has been reported on both the steam side and water side.

Carbon Steel. The major problems associated with carbon steel in FWHs are general corrosion, water-side flow-accelerated corrosion (FAC), and steam-side erosion (Ref 79, 88–92). The water-side FAC failures have occurred primarily at the tube inlets and generally are found

Fig. 12 Three-zone feedwater heater (desuperheating, condensing, and subcooling zones). Courtesy of Heat Exchange Institute

Table 7 Feedwater heater tube materials susceptibility to corrosion

Material	Susceptibility to corrosion(a)						
	General corrosion	Pitting	Crevice corrosion	FAC(b)	SCC(c)	Dealloying	Intergranular corrosion
Arsenical admiralty	H	L	L	H	H	M	H
Arsenical copper	M	M	M	H	M	L	H
Carbon steel	H	M	M	H	H	NA	H
Copper-nickel (70/30)	M	M	L	M	M	L	H
Copper-nickel (80/20)	M	M	L	M	M	L	H
Copper-nickel (90/10)	M	M	L	M	M	M	H
Monel (alloy 400)	M	M	M	M	M	L	M
Stainless steel (304)	L	H	H	L	H	NA	H

(a) Susceptibility scale: L, low; M, moderate; H, high; NA, not applicable. (b) FAC, flow-accelerated corrosion; (c) SCC, stress-corrosion cracking

in the first few heaters in the high-pressure units. On the steam side, erosion failures have occurred on the peripheral tubes because of direct steam impingement and in the drain cooling section because of condensate flashing and steam in-leakage. Unlike erosion and FAC, general corrosion of carbon steel FWHs usually is not associated with actual failures, but the corrosion product generation and transport that occurs because of general corrosion is of concern for other cycle components.

Stainless Steels. The most common stainless steel used for LP FWH tubes is type 304, which is highly resistant to general corrosion and FAC (Ref 79, 88–92). Under some circumstances, 304 stainless steel can be vulnerable to SCC, pitting, and crevice corrosion. Infrequent service failures of type 304 stainless steel in FWHs suggest that the conditions required for their occurrence are rather unlikely under normal operating conditions. There have been cases where large manganese sulfide (MnS) inclusions dissolved and caused perforation of 304 stainless steel tubes. Other stainless steels used for feedwater heaters include 304N, AL-6X, AL-6XN, type 329, type 439, and Sea-Cure.

Water and Steam Chemistry

The water chemistry factors that influence feedwater heater tube corrosion are water and steam contaminants (chloride, dissolved oxygen, etc.), fluid temperature, and the pH achieved by adjustment with ammonia (Ref 77, 79, 80, 94, 96). Systems with all steel and stainless steel components generally operate with a pH between 9.2 and 9.6 to minimize carbon steel corrosion. This limits the entrainment of corrosion products in the condensate. Problems are encountered with mixed metal systems containing both copper alloys and carbon steel. These systems are generally operated at a pH of 9.0 to 9.3. However, this range is only a compromise and is not an optimum range for the control of corrosion of either material. Recommended guidelines are available that specify control parameters and monitoring locations (Ref 94, 96).

Turbine extraction steam chemistry is, for the superheated steam extractions, the same as the turbine steam chemistry (Ref 94). The concentrations of impurities in this steam are in the low ppb range. During the heat-transfer process in feedwater heaters, the steam is desuperheated and the impurities redistribute between moisture droplets and liquid film on tube surfaces and the steam. Similarly as in the turbine, the liquid phase will have higher concentrations of low-volatility impurities, such as salts, and lower pH, because ammonia will be mostly in the gaseous phase. This will influence tube corrosion and FAC as well as FAC of the heater shell. In the zone just before condensation (slight superheats), there will be a “salt zone” in which salts and acids concentrate to percent concentrations (see the article “Corrosion of Steam Turbines” in

this Volume). Corrosion is the most severe in the salt zone.

Corrosion Problems

Corrosion mechanisms that have led to failures or serious problems in feedwater heaters include: general corrosion, flow-accelerated corrosion, stress-corrosion cracking, crevice corrosion, and pitting. Each form of failure occurs only under specific environmental and metallurgical conditions. Corrosion problems associated with common feedwater heater tube materials can be summarized:

- Flow-accelerated corrosion and erosion of tube inlets
- Cavitation
- Debris or “clamshell” pits
- Support wear
- Fatigue cracks (near supports and midspan)
- Tube-to-tube wear
- Dealloying of copper alloys
- Overrolling (at tubesheets or supports) or freeze bulges
- Stress-corrosion cracking
- Steam moisture erosion
- Corrosion, wear, and flow-accelerated corrosion at supports
- Underdeposit pitting of stainless steel
- Manufacturing defects including MnS inclusions in austenitic stainless steel

Feedwater heater corrosion and other problems are:

- Feedwater heater tube leaks, see Fig. 13
- Thinning of heater shell and piping by flow-accelerated corrosion
- Erosion of support plates and drain
- Deposition of copper alloys (snakeskin) in high-pressure heater tubes caused by general corrosion elsewhere in the system
- Loose tube plugs
- General corrosion of copper alloy tubes with redeposition in the HP turbine leading to a loss of efficiency

- Water induction and water hammer
- Phosphate hideout and boiler tube corrosion due to copper alloy tubing corrosion and deposition of zinc and nickel in boiler tubes

Tubes

The most frequent problems with feedwater heaters involve tube leaks. In spite of many possible damage locations, it is often possible to minimize any downtime by plugging a leaking or corroded tube (Ref 74).

Flow-Accelerated Corrosion. Experience has demonstrated that carbon steel tube bundles are among the components most vulnerable to flow-accelerated corrosion (FAC) (Fig. 13), although copper alloy tubes are also susceptible (Table 7) (Ref 77, 80, 83, 86, 87, 89, 92). Feedwater heater tubes are typically designed with the minimum wall thickness necessary to support the mechanical loads because a thinner wall promotes more efficient heat transfer. Therefore, even a small reduction in wall thickness due to corrosion can result in failure. The primary causes of FAC are excessive water velocities, either by poor design or by abnormal operation of the feedwater heaters, and channel geometries that result in local zones of turbulence at the tubesheet. Low feedwater pH, low oxygen concentration, and high oxygen scavenger concentration accelerate FAC.

The inlet-end of the tubes is the most susceptible. Flow-accelerated corrosion can be minimized by the use of flow diffusers in the inlet channel to reduce inlet turbulence and ensure even distribution of the flow to all tubes. Tube inserts may also be used; however, care should be taken to avoid galvanic corrosion. Other measures for preventing flow-accelerated corrosion in feedwater heater tubes include:

- Maintaining feedwater velocity within recommended limits (e.g., 1.7 to 2.4 m/s, or 5.5 to 8 ft/s, for carbon steel depending on temperature) (Ref 75)
- Evaluating design changes which could reduce or prevent FAC

Fig. 13 Flow-accelerated corrosion of carbon steel feedwater heater tubes. Courtesy of Jonas, Inc.

- Substituting more resistant tube alloys
- Maintaining water chemistry within recommended limits (Ref 94)

General corrosion occurs in all feedwater heater tube alloys (Ref 77, 80, 87–93). Corrosion rate, however, varies substantially among the tube materials. Passive materials, such as the austenitic stainless steels, usually demonstrate negligible uniform corrosion rates and are therefore considered almost immune. In general, susceptibility to general corrosion decreases as alloy selection changes from carbon steel to brass, copper-nickel, Monel 400, and stainless steel (immune). The nature of the corrosion product film is the primary controlling variable.

The variables affecting general corrosion, and therefore the corrosion product film, are pH, temperature, fluid velocity, and concentration of corrodent (e.g., O_2 , Cl, CO_2 , organic acids). The influence exerted by each variable greatly depends on the alloy selected.

Fossil plant cycling can accelerate the corrosion of carbon steel and copper alloy tubes. Typically, the highest concentrations of oxygen and CO_2 are present during low loads and during outages. Because the corrosion rate of carbon steel is directly proportional to the oxygen and carbon dioxide concentrations, greater corrosion is likely with cycling service. Cycling service also creates thermal expansion-contraction problems that arise from the difference in the thermal expansion coefficients of the carbon steel tube and its corrosion product film. This leads to repeated fracturing of the protective corrosion product film.

Deposition in Other Parts of the Cycle. General corrosion of copper alloy tubes can lead to copper transport and deposition in boilers and turbines, resulting in a loss of efficiency and megawatt (MW) generating capacity.

Snakeskin. Corrosion of admiralty brass low-pressure feedwater heater tubes can lead to a redeposition of copper on high-pressure feedwater heater tubes (Ref 87, 88). The deposition results in a thin flaky film, which resembles a snakeskin, that can cause significant reduction in the heat transfer rate. These deposits can then be released during load changes and start-up and redeposit downstream in the boiler, superheater, and HP turbine.

Maintaining water chemistry within recommended limits (Ref 94) and proper layup (Ref 95) will minimize the rate at which general corrosion occurs.

Pitting of feedwater heater tubes is generally limited to austenitic stainless steels and carbon steels (Ref 77, 80, 87, 88, 92, 93). Pitting of austenitic stainless steel alloys is caused by the contamination of feedwater by chlorides. Pitting typically occurs when chlorides are concentrated under deposits, within crevices, and through evaporation, for example, in the desuperheating zone, shell side. The few reported incidents of chloride-induced pitting in austenitic stainless steel (type 304) are generally associated with

excessive seawater intrusion permitted by condenser tube leaks. Failure to control feedwater oxygen content has also resulted in incidents of pitting in carbon steel tubing. As temperature increases, pitting resistance decreases.

Dissolution of inclusions can result in the initiation of pitting and perforation of stainless steel tubes. Manganese sulfide (MnS) inclusions are formed in stainless steels when the manganese content approaches 2%. These inclusions are soluble in water and, depending on the size of the inclusion, could result in the formation of an active site for pit initiation. Using stainless steels with low manganese concentrations reduces the size and number of inclusions.

Fouling. Poor water chemistry, corrosion products generated upstream, and condenser leakage are the primary causes of tube fouling (Ref 79). It may also be a result of inadequate initial cleaning of the system or from leaks of turbine oil into the condensate.

Corrosion of LP FWHs can cause severe tube deposits inside tubes and at the tubesheet of the HP heaters. The reason is that the concentration of corrosion products (magnetite, copper oxides) can be higher than their solubility in feedwater. To prevent fouling, feedwater chemistry should be maintained within recommended limits (Ref 94), and the feedwater heater should be cleaned as necessary.

Stress-corrosion cracking (SCC) occurs when an alloy under a tensile stress (applied and/or residual from manufacture or welding) is exposed to a specific corrosive environment (Ref 77, 80, 87–93). Failures due to SCC in feedwater heaters have not been significant in number, and gross deviation from normal feedwater chemistry is the universal cause. The potential for concentration of corrosive chlorides occurs mainly on the shell side in the desuperheating zone in the event of a small leak. In the feedwater heater desuperheating zone, salts and acids can be present as very corrosive concentrated aqueous solutions. This is a similar situation to the “salt zone” corrosion occurring in turbines.

Copper alloys are susceptible to NH_3 -induced SCC, with brass (copper-zinc) exhibiting the highest stress-corrosion crack growth rates. Stress-corrosion cracking can be minimized by reducing the residual stresses in the material, for example, by stress relieving tube U-bends. Because of the susceptibility of copper alloys to other corrosion mechanisms and because of the overall need to reduce copper within the system, the use of copper alloys has been greatly diminished.

The limits of chloride and oxygen in water for avoiding stress-corrosion cracking of type 304 stainless steel are well known, and the limits for avoidance of pitting are similar. There have been a few reported SCC failures in Monel 400 tubes, primarily at the U-bend.

Exfoliation. Typically, exfoliation occurs preferentially along the boundaries of grains that were elongated during tube fabrication (Ref 80, 87, 88). The water insoluble corrosion

products that form produce expansion forces sufficient to forcibly separate the elongated grains. The 70Cu-30Ni and 80Cu-20Ni alloys are susceptible to exfoliation, and susceptibility increases with increasing alloy nickel content. The 90Cu-10Ni alloy is immune to exfoliation (Ref 80).

Tubes that have experienced this form of corrosion exhibit heavy scaling, which has a distinct “leafy” (laminated) appearance. The scale material is composed of copper and nickel oxides in approximately the same proportion as the copper and nickel content of the specific alloy.

Oxygen is a critical corrodent in the exfoliation process, and peaking/cycling service increases the rate of exfoliation due to greater and more frequent exposure to oxygen.

Tube-to-Tubesheet Joint

Crevice corrosion often starts at the back of a tube-to-tubesheet joint weld where the manufacturer did not adequately expand the tube into the tubesheet after welding (Ref 77, 80, 92, 93). Stagnant water and crud that can be in constant contact with the weld nugget may eventually corrode the weld, especially in a vertical channel down design. When this happens, a worm-hole condition is established that can work its way into the face of the tube inlet. Once this penetration is made, it is aggravated by the pressure differential from the channel to the shell; rapid erosion occurs, resulting in catastrophic tube-to-tubesheet failure. In some cases, the tube-to-tubesheet joint weld failed around the complete circumference, and the separated tube end was found by boroscopic examination beyond the back of the tubesheet. Failures of this kind allow large volumes of water to enter the shell and possibly the turbine before being detected.

Heater Shell

The shell of a feedwater heater is normally carbon steel and is susceptible to general corrosion and flow-accelerated corrosion.

Flow-Accelerated Corrosion. Thinning from flow-accelerated corrosion (FAC) has been detected on the carbon steel shells of feedwater heaters and is caused by the two-phase flow inside the shell (Ref 80, 85). Most feedwater heaters also use carbon steel tube support plates and flow baffles, which are also subject to FAC. Some long-term erosion in the condensing zone is unavoidable.

Corrosion of Flue Gas Desulfurization Systems

W.L. Mathay, Nickel Institute

AIR POLLUTION is a world-wide concern that can adversely affect the environment, structures, and human health. It is a major contributor to acid rain, which occurs as a result of sulfur oxide emissions being converted into acids in the atmosphere. These emissions can be carried long distances by the prevailing winds and can fall to earth with rain, creating very acidic conditions at ground level. It has long been recognized that coal-burning power plants are the major source of sulfur oxides, and along with vehicles and other combustion units, a major source of nitrogen oxides, another significant pollutant.

Recognizing the need to control acid rain, the U.S. Environmental Protection Agency (EPA) began establishing sulfur dioxide (SO_2) emission restrictions and time frames for compliance beginning in the 1960s and continuing through the 1990s. During the latter period, restrictions on emissions of nitrogen oxides (NO_x) were also established. These restrictions and others dealing with toxic metals and particulates continue to be adjusted as environmental conditions dictate. In recent years, other countries with coal-burning power plants have adopted SO_2 and NO_x emission restrictions as well.

Flue Gas Desulfurization (FGD) Technology

Numerous methods for controlling SO_2 emissions have been investigated, with most of the emphasis being placed on systems for the removal of SO_2 from power-plant flue gases. In these systems, combustion gases generated by the firing of coal are sent to scrubbing equipment where SO_2 is removed by reaction with an absorbing slurry, solution, or reactant. At one time there were over 250 flue gas desulfurization (FGD) processes under consideration, but wet lime/limestone scrubbing with the production of gypsum as a by-product has become the most widely used process because of its high removal efficiency and operational reliability. These efficiencies have been improved to the point

where SO_2 removal rates of over 95% have become common. In addition, forced-air oxidation has been used to control the oxidation of reaction products, decrease scaling, and aid in the production of commercial-grade gypsum for wallboard production.

Inasmuch as wet scrubbers have become the predominant method of SO_2 emissions control, their use in NO_x control also has been considered. However, they are ineffective in reducing NO_x emissions because of the relative insolubility of nitrogen oxides in water. Thus, power plant operators turned to the use of low-nitrogen-oxide burners, changes in firing practice, and the installation of selective catalytic reduction (SCR) systems. The SCR system uses a catalyst that promotes reaction of the nitrogen oxides with ammonia to produce nitrogen and water from the nitrogen oxides (Ref 1). However, the use of SCR systems can lead to the formation of additional sulfur trioxide (SO_3) beyond that which is formed during the coal combustion process. Ultimately, the SO_3 can react with water to form sulfuric-acid-mist aerosols that escape the scrubber as fine particulates. Scrubbers are highly efficient in absorbing SO_2 but are inadequate in capturing the SO_3 aerosols that can result in the formation of a very visible acid plume exiting the chimney.

FGD Corrosion Problem Areas

A number of years ago, in order to understand the corrosion problems encountered in wet scrubbing, the American Society for Testing and Materials (now ASTM International) prepared a special technical publication, STP 837, which presented a simplistic generic FGD system and attempted to define the associated corrosion problem areas (Ref 2). Initially, a prescrubber leading into the main scrubber or absorber was used primarily for prequenching and particulate control. However, later designs eliminated the prescrubber and brought the hot flue gases from the electrostatic precipitator directly into the absorber, as shown in Fig. 1 (Ref 3).

There are a number of FGD designs involving different flue gas/scrubbing medium contact methods, but in the commonly used spray tower, similar to the generic scrubber, the flue gas is brought into the lower part of the absorber at temperatures ranging from 149 to 182 °C (300 to 360 °F) and is quenched by counter-current sprays of the scrubbing medium. Corrosion can be quite severe in the quench area because wet-dry zones occur near the flue gas inlet, causing scale deposition. Crevice corrosion can occur beneath these deposits because of the presence of chlorides and possibly fluorides from the coal and the low pH values that develop as corrosion proceeds in an autocatalytic manner. The potential severity of the problem is best shown by the fact that chloride concentrations as high as 100,000 ppm have been found beneath the scale deposits. Scale deposition and corrosion also can extend into the inlet duct because of the carry-back of the scrubbing medium and its reaction with the hot, incoming flue gas. Usually the most corrosion-resistant materials are required in this area.

In the absorber sump or recycle tank below the liquid level, there may be concerns about erosion because of the solids content of the scrubber slurry. In some cases FGD designers have chosen to use thicker alloys to avoid the problem.

As the flue gas leaves the wet-dry or quench zone and travels up through the absorber and the mist eliminator area, usually much less corrosive conditions are encountered. The gas temperature drops to about 50 to 65 °C (122 to 149 °F) and the pH value of the environment generally rises, allowing the use of less corrosion-resistant materials. However, under certain circumstances improved boiler efficiencies may lead to greater flue gas velocities, which can result in "blow-through" of the corrosives from the lower part of the absorber. Thus, the environment approaching the absorber outlet may remain quite aggressive and dictate the use of materials similar to those used in the lower part of the absorber above the wet-dry zone.

In the outlet duct and into the chimney liner, the environment again can become quite corrosive because the scrubbed gas is saturated with

Qualitative definition of operating zones

Code	Chemistry	Mechanical environment	Temperature
A	Mild corrosive (vapor)	Mild	Mild
B	Moderate (immersion)	Mild	Mild
C	Moderate	Moderate	Mild
D	Moderate	Severe	Mild
E	Severe	Mild	Moderate
F	Severe	Mild	Severe
G	Severe	Severe	Severe

Fig. 1 Operating zones for generic FGD system, ASTM D-33.09 modified. Source: Ref 3

moisture and contains sulfur acids of varying concentrations as well as possibly hydrochloric and hydrofluoric acids. These acids may condense in the outlet duct and in the chimney liner, causing serious corrosion problems. Currently there are a number of FGD installations that have bypass ducts that can introduce hot, unscrubbed flue gas into the scrubbed gas stream and increase the severity of the acid attack. However, newer designs generally have eliminated the bypass ducts because of SO_2 emission restrictions.

In the past, several types of reheaters have been used in the outlet duct, but their use has been abandoned because of the many corrosion problems encountered with the reheaters. Thus, the use of the so-called 'wet-stack' has become common practice. In a wet-stack, materials that are resistant to acid attack at the temperatures involved must be used.

If a plant has installed an SCR system for NO_x capture, it may need to install a wet electrostatic precipitator (WESP) with several electrical fields following the absorber to capture the SO_x aerosols that are not removed in the absorber (Ref 4). One plant has integrated the absorber and the WESP, with the flue gas flowing up through the absorber and then through the WESP before passing through a final mist eliminator. After leaving the final mist eliminator, the flue gas passes through an outlet hood and duct and then enters the chimney liner.

Materials Selection for FGD Components

To comply with environmental emission restrictions, air pollution control systems must utilize corrosion-resistant construction to ensure availability and reliability. The corrosion problem areas have been determined and the major forms of corrosive attack encountered; crevice corrosion, pitting corrosion, and acid attack have been identified. Design features that minimize the possibility of corrosion in certain components also have been recognized. These include the sloping of ducts to avoid puddling of liquids, and the use of welding procedures that provide low profile, smooth welds to avoid scale build-up and crevice corrosion.

A number of materials have been used to minimize corrosion problems in FGD systems, but initial cost is often a determining factor. For example, flake-glass-filled organic coatings and linings on carbon steel have been used for absorbers and ductwork because of low initial costs. However, inadequate surface preparation and improper application can result in short service lives and lead to costly touch-ups and/or recoating.

If properly applied and cured, rubber linings on carbon steel have performed well in absorbers, slurry piping, and pumps, but some can become brittle and can blister from water

absorption. Periodic repairs and maintenance may be required, resulting in costly outages.

Acid-resisting bricks and mortar have been used successfully for many years as chimney liners. Problems with mortar permeability and substrate corrosion, as well as the need for increased foundation support, can be deterrents to usage.

In recent years, borosilicate-glass blocks have found application in outlet ducts and as chimney liners because of their corrosion-resisting and insulating properties. However, care must be taken to avoid surface damage to the blocks that can lead to liquid penetration and deterioration of the membrane backing.

Fiberglass reinforced plastic (FRP) laminates can be cost-effective materials for absorbers, ductwork, slurry piping, and chimney liners. For satisfactory performance they require good quality control procedures throughout fabrication and installation, and adequate support after fabrication.

Titanium-sheet linings and intermittently bonded cladding on carbon steel have been used for outlet ductwork and chimney liners. Again, proper fabrication and installation procedures are necessary. Titanium has generally good corrosion resistance but can be severely attacked by fluorides.

Although each of the foregoing materials may offer certain advantages, nickel-containing alloys are increasingly preferred for FGD service. They are readily fabricated and installed and, when properly selected, offer excellent corrosion resistance along with long-term reliability at low life-cycle costs.

The nominal chemical compositions of the various alloys considered for use in FGD systems are shown in Table 1. Included in generally increasing corrosion-resistance order are the austenitic stainless steels, types 316L (UNS S31603) and 317L (S31703), and the 4% molybdenum stainless steels, types 317LM (S31725), 317LMN (S31726), and 904L (N08904). (For the most part, alloy 904L has been replaced by type 317LMN.)

Next are the austenitic/ferritic duplex and super duplex stainless steels, typified by alloys 2205 (S31803 and S32205) and 2507 (S32750), respectively, the 6 to 7% Mo super austenitic stainless steels, a 9% Mo-Ni, alloy 625 (N06625), and the 13 to 16% Mo-Ni alloys. Of this latter group, alloy C-276 (N10276) and C-22 (N06022) were the most corrosion-resistant FGD alloys available until alloy 59 (N06059), alloy 686 (N06686), and alloy C-2000 (N06200) were developed to provide greater corrosion resistance.

The user has the option of using the stainless steels and nickel alloys as sheet linings on carbon steel (often called wallpapering), as alloy-clad carbon-steel plate, or as solid alloys, with the selection being determined by cost and overall project considerations. NACE International has developed detailed instructions for the installation of metallic wallpaper sheet linings (Ref 5) and alloy-clad plate (Ref 6) in air pollution

control equipment. Usually there is no cost advantage to the use of the lower-alloyed stainless steels as sheet linings or clad plate over solid plate. However, the higher alloys, particularly those containing 13 to 16% Mo, when used as 1.6 mm (0.0625 in.) thick sheet linings or cladding can be economically attractive (Ref 7).

As for the specific applications for the foregoing constructional materials, types 316L and 317L stainless steels are used for some low-chloride absorber applications. However, increased chloride levels are being encountered in the scrubbing slurries as plants have moved toward zero-discharge of liquids. This increase in chloride levels has dictated the application of more corrosion-resistant absorber materials. The 4% and 6 to 7% Mo stainless steels and alloys C-276 and C-22 have been used depending on pH and chloride levels. The duplex and super duplex stainless steels are also finding increased usage in place of the 300-series stainless steels.

For the very corrosive wet-dry zones in the absorber inlet and inlet duct, the high Ni-Cr-Mo alloys such as alloy C-276 are usually specified. By contrast, at the top of the absorber in the mist eliminator area, types 316L and 317L stainless steels have been used successfully. If "blow-through" conditions exist, higher alloys such as the 4 to 6% molybdenum alloys should be considered.

In the outlet duct and in the chimney liner, alloys resistant to the acid concentrations and temperatures that can occur are shown in Fig. 2 (Ref 3). In many instances, alloy C-276 or a higher alloy has been used, usually as sheet linings or clad plate, to provide the desired corrosion resistance.

Often, spray piping in the absorber is fabricated of FRP, rubber-lined or covered-steel, or a high-alloy material such as alloy C-276. Absorber internals and supports usually are fabricated of the same alloy as the absorber, although some use has been made of duplex stainless steels. Pumps and other items of equipment also make use of rubber-covered components and duplex and super duplex stainless steels.

In those installations where there is a WESP following the absorber, the 4 to 6% Mo stainless steels have been used for the casing and most of the internal structures and components. However, because the flue gas entering the WESP contains high levels of sulfuric acid and chlorides, materials such as alloy C-276 may be required. Alternatively, FRP has been used.

Numerous laboratory and field corrosion tests as well as service performance studies have been used to evaluate alloys and to develop alloy comparisons for use in FGD systems. In this regard, comparisons of alloys have been aided by the use of Pitting Resistance Equivalent Numbers (PREN). The PREN values are calculated using equations involving alloying elements such as chromium (Cr), molybdenum (Mo), and nitrogen (N) that are important to providing pitting corrosion resistance. The higher the PREN value, the greater the corrosion resistance of the alloy. One of the earliest equations

used was $PREN = \%Cr + 3.3 (\%Mo) + 16(\%N)$. Although initially applied to stainless steels, the equation has been extended to include nickel-base alloys, and in many instances the nitrogen multiplier has been increased from 16 to 30. Alloy producers regularly provide PREN equations and values in their literature, including both stainless steels and nickel-base alloys.

More definitive alloy selection assistance is available from the use of charts such as Fig. 3 (Ref 1). This chart offers suggested guidelines for the selection of stainless steels and nickel alloys for FGD equipment based on chloride levels and pH values at the absorber operating temperatures of 50 to 65 °C (122 to 149 °F). However, when using this type of information, it

is important to remember that each FGD system is somewhat unique, no matter how similar in design.

Future Air Pollution Control Considerations

For the foreseeable future, coal will continue to be a major fuel for power generation. New and retrofitted FGD systems will continue to be installed. Governmental regulations will continue to call for further reductions in emissions of SO_x and NO_x , as well as reductions in particulates and toxic metals such as mercury.

Table 1 Nominal chemical compositions of metals considered for flue gas desulfurization service

Common name	UNS No.	Composition, wt%								
		Cr	Ni	Mo	Fe	Co	W	Cu	C	Other
316L	S31603	17	12	2.2	bal	0.03	0.05 N

Both wet and dry FGD scrubbing systems will be used for SO₂ emission control, depending upon the type of coal burned. Systems for reducing NO_x, sulfuric acid aerosols, fine particulates, and toxic metal emissions will be required. Thus in the United States, because existing and proposed federal emission standards involve multiple pollutants, multi-pollutant control technologies must be considered from an economic standpoint.

The U.S. Environmental Protection Agency has recognized the fact that there is a significant relationship between SO₂, particulates, and toxic metals. Power plants burning high-sulfur coals and equipped with wet scrubbers are said to be able to remove up to 90% of particulate heavy metals (Ref 8). The addition of a WESP to the scrubbing system will result in the capture of sulfuric acid aerosols that escape the scrubber and will aid further in the removal of fine particulates and metals.

The removal of mercury poses a problem because its capture requires that it be in the ionic or oxidized form. Wet scrubbers at plants burning high-sulfur coals apparently can remove most of the oxidized mercury present in the flue gas reaching the scrubber. Research indicates that the catalysts in SCR installations that are ahead of the scrubber can oxidize the elemental mercury with the gas, thus increasing mercury removal by the scrubbers. However, plants burning low-sulfur coal appear to emit mercury that is mostly elemental. Dry scrubbers and activated carbon injections with fabric filters for

particulate and mercury collection are being considered for low-sulfur coal-burning plants.

As yet, the integration of processes to control multiple-pollutant emissions has not made significant progress because of the lack of information on the economics involved. Also, integration with existing pollution control equipment must be considered if retrofit installations are to be made.

Corrosion of Steam- and Water-Side of Boilers

Phillip Daniel, Babcock & Wilcox Company

HIGH-TEMPERATURE WATER AND STEAM react with boiler steel to form oxides, hydroxides, hydrates, and hydrogen, but formation of a protective oxide layer, such as magnetite (Fe_3O_4), on the metal surface generally impedes further reaction. Such protective oxide films are maintained and corrosion prevented by appropriate control of boiler water chemistry. However, excessive impurities in boiler feedwater can prevent effective control, form harmful deposits, and aggravate corrosion. Although deposition, corrosion, and chemistry control processes vary with boiler pressure and cycle design, similar processes are involved for a wide range of power boilers and for many industrial boilers and heat-recovery steam generators as well.

Chemistry-Boiler Interactions

As steam forms, dissolved solids concentrate in the boiler water. Where the solubility of an impurity is exceeded, steam formation may leave behind precipitated deposits. These deposits in turn provide a sheltered environment that further increases chemical concentrations and deposition rates. In a clean boiler tube, concentration of chemicals at the tube surface is limited by free exchange of fluid between the surface and boiler water flowing through the tube. Even where there are thin deposits, boiling generally produces sufficient flow within the deposits to limit the degree of concentration. However, as deposits accumulate, they restrict flow to the surface.

Typical boiler deposits are largely hardness precipitates (calcium and magnesium salts) and metal oxides. The nature of these deposits is typically a function of the makeup water purification system. Hardness deposits are most common with softened makeup water, while metal oxides are more likely with demineralized or reverse-osmosis-type makeup water. Most hardness salts are easily precipitated due to their retrograde solubility. Hardness salts can enter the cycle as impurities in makeup water and in cooling water from condenser leaks. Metal oxides are largely from corrosion of preboiler cycle components. Scaling occurs when these minerals

and oxides precipitate and adhere to boiler internal surfaces, where they impede heat transfer. The result can be overheating of tubes, sometimes followed by failure of tubes if corrective measures are not taken. Deposits can also increase boiler circuit pressure drop in forced circulation boiler systems.

As they concentrate, some chemicals become corrosive. Corrosion can occur even in a clean boiler, but the likelihood of substantial corrosion is much greater beneath thick porous deposits that facilitate the concentration process. The concentration beneath deposits can be more than 1000 times higher than that in the bulk boiler water, and the temperature at the base of these deposits can substantially exceed the saturation temperature. As deposits accumulate, control of boiler water chemistry to avoid the formation of corrosive concentrates becomes increasingly important and difficult. Hence, operation of a boiler with excessively thick deposits must be avoided.

Although separation devices remove most water droplets carried by steam, some residual droplets containing small amounts of dissolved solids always carry through with the steam. Also, at higher pressures, there is some vaporous carryover. Excessive carryover of impurities can damage superheaters, steam turbines, or downstream process equipment.

Corrosion Control and Prevention

Deposition and corrosion in boilers are controlled by water purification and chemical treatment. Impurities are removed by purification of makeup water, polishing of returned condensate, deaeration, and blowdown. Chemicals are then added to control pH, electrochemical potential, and dissolved oxygen concentration. Care must also be taken to prevent corrosion when boilers are out of service, on standby or for maintenance. Proper water chemistry control improves boiler reliability and reduces maintenance and component replacement costs. It also improves performance and life of heat exchangers, pumps, turbines, and piping throughout the steam generation, use, and condensation cycle.

General water chemistry control limits and guidelines have been developed and issued by various groups of boiler owners and operators (e.g., American Society of Mechanical Engineers, Ref 1–3; Electric Power Research Institute, Ref 4; and Vereinigung der Grosskraftwerkbetreiber, Ref 5), water treatment specialists, utilities, and industries. Also, manufacturers provide recommended chemistry control limits for each boiler and for other major cycle components. However, optimal water and steam chemistry limits for boilers, turbines, and other cycle components depend on equipment design and materials of construction for the combination of equipment employed. Hence, for each boiler system, boiler-specific water chemistry limits and treatment practices must be developed and tailored by competent specialists familiar with the specific boiler and its operating environment.

In addition to customized boiler-specific guidelines and procedures, qualified operators are essential, and vigilance is required to detect early signs of chemistry upsets. Operators responsible for plant cycle chemistry must understand boiler water chemistry guidelines and how they are derived and customized. They must also understand how water impurities, treatment chemicals, and boiler components interact. Training must therefore be an integral, ongoing part of operations and should include management, control room operators, chemists, and laboratory staff. Training and plant operating procedures must also address safety and health hazards associated with boiler operation, with steam and water sampling, and with chemicals used for water purification and treatment. If not handled properly, many of these operations and chemicals can pose severe safety and health hazards.

Common Fluid-Side Corrosion Problems

With adequate control of water and steam chemistry, internal corrosion of boiler circuitry can be avoided. Yet, chemistry upsets (transient

losses of control) do occur. Where preventative measures fail and corrosion occurs, good monitoring and documentation of system chemistry can facilitate identification of the root cause. Identification of the root cause is an essential step toward avoidance of further corrosion. Where corrosion occurs and the cause is unknown, the documented water chemistry, location of the corrosion, appearance of the corrosion, and chemistry of localized deposits and corrosion products often suggest the cause. Common causes are flow-accelerated corrosion, oxygen pitting, chelant corrosion, caustic corrosion, acid corrosion, organic corrosion, phosphate corrosion, hydrogen damage, and corrosion-assisted cracking. Additionally, pitting and microbiological corrosion can occur under poor lay-up conditions. Further discussion of corrosion and failure mechanisms is provided in Ref 6 to 9.

One distinguishing feature of corrosion is its appearance. Metal loss may be uniform, so the surface appears smooth. Conversely, the surface may be gouged, scalloped, or pitted. Other forms of corrosion are microscopic in breadth, and subsurface, so they are not initially discernable. Subsurface forms of corrosion include intergranular corrosion, corrosion fatigue, stress-corrosion cracking, and hydrogen damage. Such corrosion can occur alone or in combination with surface wastage. In the absence of component failure, detection of subsurface corrosion often requires ultrasonic, dye penetrant, or magnetic-particle inspection. These forms of corrosion are best diagnosed with destructive cross-sectional metallography.

Another distinguishing feature is the chemical composition of associated surface deposits and corrosion products. Deposits may contain residual corrosives such as caustic or acid. Magnesium hydroxide in deposits can suggest the presence of an acid-forming precipitation process. Ferrates and sodium carbonate indicate caustic conditions. Sodium-iron phosphate indicates phosphate wastage. Organic deposits suggest corrosion by organics, and excessive amounts of ferric oxide or hydroxide with pitting suggest oxygen attack.

Flow-accelerated corrosion is the localized dissolution of feedwater piping in areas of flow impingement. It occurs where metal dissolution dominates over protective oxide scale formation. For example, localized conditions are sufficiently oxidizing to form soluble Fe^{2+} ions but not sufficiently oxidizing to form Fe^{3+} ions needed for protective oxide formation. Conditions known to accelerate thinning include flow impingement on pipe walls, low pH, excessive reducing agent (oxygen scavenger) concentrations, chemicals that increase iron solubility, and thermal degradation of organic chemicals. Thinning can occur at any feedwater temperature, but it is most rapid in the range of 120 to 205 °C (250 to 400 °F). Thinned areas often have a scalloped or pitted appearance. Feedwater piping failures, such as that shown in Fig. 1, can occur unexpectedly and close to work areas and walkways. To ensure continued integrity of

boiler feedwater piping, it must be periodically inspected for internal corrosion and wall thinning. Any thinned areas must be identified and replaced before they become a safety hazard. The affected piping should be replaced with low-alloy chromium-bearing steel piping, and the water chemistry control should be appropriately altered.

Oxygen pitting and corrosion during boiler operation largely occur in preboiler feedwater heaters and economizers, where oxygen from poorly deaerated feedwater is consumed by corrosion before it reaches the boiler. However, oxygen pitting within boilers occurs when poorly deaerated water is used for startup or for accelerated cooling of a boiler. It also occurs in feedwater piping, drums, and downcomers in some low-pressure boilers that have no feedwater heaters or economizer. Oxygen pitting is often characterized by well-formed, relatively deep and rounded pits surrounded by passive zones of little or no corrosion. Because increasing scavenger concentrations to eliminate residual traces of oxygen can aggravate flow-accelerated corrosion, care must be taken to distinguish between oxygen pitting and flow-accelerated corrosion, which generally occurs only where all traces of oxygen have been eliminated.

Complexing agent corrosion occurs where appropriate feedwater and boiler water chemistries for chelant or some polymer treatments used in some low-pressure boilers are not maintained. Potentially corrosive conditions include low pH or excessive concentration of free chelant and dissolved oxygen or polymer. Especially susceptible surfaces include flow impingement areas of feedwater piping, riser

tubes, and cyclone steam/water separators. Affected areas are often dark colored and have the appearance of uniform thinning or flow-accelerated corrosion.

Corrosion fatigue is cracking well below the yield strength of a material by the combined action of corrosion and alternating stresses. Stress may be of mechanical or thermal origin. In boilers, corrosion fatigue also occurs in ferritic and austenitic superheaters, but it is most common in water-wetted surfaces where there is a mechanical constraint on the tubing. For example, corrosion fatigue occurs in furnace wall tubes adjacent to windbox, buckstay, and other welded attachments. Failures are thick lipped, with little or no reduction in wall thickness. On examination of the internal tube surface, multiple initiation sites are evident. Cracking is transgranular. Environmental conditions facilitate fatigue cracking where it would not otherwise occur in a benign environment. One such factor is low-pH transients associated with, for example, cyclic operation, condenser leaks, and phosphate hideout and hideout return.

Phosphate corrosion occurs on the inner steam-forming side of boiler tubes by reaction of the steel with phosphate to form maricite (NaFePO_4). Figure 2 shows ribbed tubing that has suffered this type of wastage. The affected surface has a gouged appearance, with maricite, hematite, and magnetite deposits. Phosphate corrosion occurs predominantly in boilers experiencing phosphate hideout. Although not always apparent, common signs of phosphate corrosion include difficulty maintaining target phosphate concentrations, phosphate hideout and pH increase with increasing boiler load or pressure, phosphate hideout return and decreasing pH with decreasing load or pressure, and periods of high iron concentration in boiler water. Potential for phosphate corrosion increases with increasing internal deposit loading, low effective sodium-to-phosphate molar ratios, increasing phosphate concentration, inclusion of low-molar-ratio phosphates (disodium and especially monosodium phosphate) in phosphate feed solution, and increasing boiler pressure. To avoid acid phosphate corrosion,

Fig. 1 Feedwater pipe thinning and rupture

Fig. 2 Acid phosphate corrosion of ribbed tubing

operators should monitor boiler water conditions closely, ensure accuracy of pH and phosphate measurements, ensure purity and reliability of chemical feed solutions, ensure that target boiler water chemistry parameters are appropriate and are attained throughout boiler load changes, and watch for signs of phosphate corrosion. Phosphate corrosion in high-pressure utility boilers may be addressed with equilibrium phosphate chemistry control.

Underdeposit acid corrosion and hydrogen damage occur where boiler water acidifies as it concentrates beneath deposits on steam-generating surfaces. Hydrogen from acid corrosion diffuses into the steel, where it reacts with carbon to form methane. The resultant decarburization and methane formation weakens the steel and creates microfissures. Thick-lipped failures occur when the degraded steel no longer has sufficient strength to hold the internal tube pressure. Signs of hydrogen damage include underdeposit corrosion, thick-lipped failure, and steel decarburization and microfissures. The corrosion product from acid corrosion is mostly magnetite. Affected tubing, which may extend far beyond the failure, must be replaced. The boiler must be chemically cleaned to remove internal tube deposits, and boiler water chemistry must be altered or better controlled to prevent acid formation as the water concentrates. Operators should reduce acid-forming impurities by improving makeup water, reducing condenser leakage, or using condensate polishing. For drum boilers, operators should use phosphate treatment with an effective sodium-to-phosphate molar ratio of 2.8 or greater.

Caustic corrosion, gouging, and grooving occur where boiler water forms a caustic residue as it evaporates. In vertical furnace wall tubes, this occurs beneath deposits that facilitate a high degree of concentration, and the corroded surface has a gouged appearance. In inclined tubes where the heat flux is directed through the upper half of the tube, caustic concentrates by evaporation of boiler water in the steam space on the upper tube surface. Resulting corrosion is in the form of a groove that is generally free of deposits and centered on the crown of the tube. Deposits associated with caustic gouging often include Na_2FeO_4 . To prevent reoccurrence of caustic gouging, operators should prevent accumulation of excessive deposits and should control water chemistry so that concentration of boiler water does not form caustic. The latter can generally be

achieved by ensuring appropriate feedwater chemistry with coordinated or congruent phosphate boiler water treatment, taking care to control the effective sodium-to-phosphate molar ratio as appropriate for the specific boiler and the specific chemical and operating conditions. In some instances, where caustic grooving along the top of a sloped tube is associated with steam/water separation, better mixing can be maintained by the use of ribbed tubing.

Caustic stress-corrosion cracking can occur where caustic concentrates in contact with steel that is highly stressed. Caustic cracking is rare in boilers with all welded connections. This generally occurs in boilers using a high-alkalinity caustic boiler water treatment, and it is normally associated with unwelded rolled joints and welds that are not stress relieved. Caustic stress-corrosion cracking at a rolled tube joint generally requires a roll leak that produces very high caustic concentrations at this location when the boiler water flashes to steam. On metallographic examination, caustic cracking is intergranular and has the branched appearance characteristic of stress-corrosion cracking. It can generally be avoided by use of coordinated phosphate treatment. Where a high-alkalinity caustic phosphate boiler water treatment is used for low-pressure boilers, nitrate is often added to inhibit caustic cracking.

Stress-corrosion cracking also occurs in superheaters and reheaters, usually in austenitic stainless steel elements where contaminants concentrate as standing water evaporates during boiler startups. Cracking occurs in areas of high stress associated with bends, welds, and attachments. Potential for stress-corrosion cracking can be minimized by control of carryover, attemperation water, chemical cleaning procedures, and out-of-service conditions to minimize contamination, especially contamination with hydroxide, chloride, or sulfide.

Out-of-service corrosion is predominantly oxygen pitting. Pitting attributed to out-of-service corrosion occurs during outages but also as aerated water is heated when boilers return to service. Especially common locations include the waterline in steam drums, areas where water stands along the bottom of horizontal pipe and tube runs, and lower bends of pendant superheaters and reheaters. Pinhole failures are more common in thinner-walled reheater and economizer tubing. Such corrosion can be minimized by following appropriate lay-up procedures for

boiler outages and by improving oxygen control during boiler startups.

Corrosion of Steam Turbines

Otakar Jonas, Jonas, Inc.

THE STEAM TURBINE (see Fig. 1) is the simplest and most efficient engine for converting large amounts of heat energy into mechanical work. As the steam expands, it acquires high velocity and exerts force on the turbine blades. Turbines range in size from a few kilowatts for one-stage units to 1500 MW for multiple-stage multiple-component units comprising high-pressure, intermediate-pressure, and up to three double-flow low-pressure turbines. For mechanical drives, single-, double-, and multiple-stage turbines are generally used. Most larger modern turbines are multiple-stage axial-flow units. Turbine inlet steam pressure and temperature conditions are governed by the boiler and range from less than 1.4 MPa (200 psi) saturated to more than 35 MPa (5000 psi) at 650 °C (1200 °F) superheated and supercritical. See the article "Corrosion in Supercritical Water—Ultrasupercritical Environments for Power Production" in this Volume. Steam is often extracted from the turbine for heating of feedwater and used in industrial processes. It is exhausted as wet subatmospheric steam, with up to 12% moisture (Fig. 7), into a condenser or at higher than atmospheric pressure for use as process steam.

Turbines are typically designed for a 25 to 40 year life. During this long life, corrosion and other material damage can accumulate and lead to premature failures. Corrosion usually results from a combination of water chemistry, design, and materials selection problems (Ref 1–67).

The cost of corrosion to U.S. fossil power plants in 1998 was estimated to be \$4.6 billion, which was equivalent to \$9 million/GW of installed capacity. Of that, corrosion fatigue (CF) and stress-corrosion cracking (SCC) in low-pressure (LP) utility turbines accounted for over \$600 million (Ref 2). The cost of industrial steam turbine corrosion is estimated to be similar. Data collected by the North American Electric Reliability Council for 1476 fossil units between 1996 and 2000 show that LP turbines were responsible for 818 forced and scheduled outages and deratings, costing the utilities 39,574 GWh (Ref 68). In the list of steam cycle component contribution to forced and planned outages, steam turbines have been in the top ten for 30 years. These outages are often character-

ized as low-frequency, high-impact events. For example, LP turbine disc SCC can result in a 6 month long outage for a new or weld-repaired rotor, costing over \$100 million, mostly for lost production.

Steam Turbine Developments

To reduce LP turbine SCC problems, most shrunk-on discs have been redesigned and replaced (Ref 13–21). Many LP rotors with shrunk-on discs have been replaced by integral or welded rotors. Weld repair techniques for the disc-blade attachment areas were developed, including weld repair of the low-alloy steel disc with 12Cr stainless steel (Ref 16). Marginally designed LP turbine blades have been replaced by better designs with reduced vibration excitation and with blades without tenon-to-shroud crevices (with integral shroud sections) (Ref 2, 3, 6). Mixed-tuned blade rows are being used for longer blades where neighboring blades do not have similar resonance frequencies. Computational flow dynamics and viscous flow modeling are used for the blade path design and development of new blade shapes (banana blades) and profiles. Better steam chemistry and cycle chemistry monitoring are resulting in better control of local corrosive environments on blade and disc surfaces. Extending turbine inspection intervals up to 10 years is bringing higher demands on steam purity and on the evaluation of inspection results, such as pitting and cracking.

Major Corrosion Problems in Steam Turbines

Corrosion fatigue, SCC, pitting, and erosion-corrosion are the primary corrosion mechanisms in steam turbines (Ref 1–37). In addition, there is water droplet erosion of last rows of LP turbine blades (Ref 2, 3, 6, 29, 38) and solid-particle erosion in the high-pressure and intermediate-pressure turbines and turbine valves caused by exfoliation of oxides in superheaters, reheaters, and steam piping (Ref 3–6, 8). There have also been cases of SCC of the crossover pipe stainless

steel and Inconel expansion bellows (Ref 1, 2, 5–7, 26). Figure 1 and Table 1 indicate the distribution of corrosion within the turbine. Pitting and CF of turbine blades and SCC of discs are currently the two costliest problems. Much research has been devoted to these two problems (Ref 1–10, 13–24), and progress has been made in both operation (better steam chemistry) and design (lower stresses, no tenon crevices, limit on maximum strength to reduce susceptibility to SCC).

It is estimated that inadequate mechanical design (use of high-strength materials susceptible to environmental cracking, high steady and vibratory stresses, stress concentration, and vibration) is responsible for approximately 50% of the problems, inadequate steam chemistry for approximately 20%, and marginal thermodynamic and flow design for approximately 20%. Poor manufacturing and maintenance practices account for the remaining 10% of the problems. The root cause of most corrosion-related outages is design, with high local stresses in discs and blades and flow excitation of blades playing the major role. Stress-corrosion cracking of blade attachments (Ref 1–3, 5–7, 13–16) and erosion-corrosion of wet-steam piping (Ref 1–3, 5, 28) seem to be generic problems, particularly in nuclear turbines.

Blade failures (Ref 1–7, 22, 23, Fig. 1) are most frequent (in fossil utility turbines) in the last minus-one row (L-1), which is at or immediately before the saturation line (Ref 1–3, 9–12, 22, 23). In industrial turbines, blade failures are also most frequent in the stages in which first moisture occurs (Ref 51). Blade pitting and cracking had been more frequent in once-through boiler units (these units used all-volatile water treatment and condensate polishers) than in drum boiler units. This was attributed to better neutralization of acids and salts by sodium phosphate in the drum boilers (Ref 35). Statistics from Germany, the United Kingdom, and Japan indicate a very low incidence of blade failures. Typical locations of CF cracks are shown in Fig. 1. A cracked L-1 blade is shown in Fig. 2, and a CF (Goodman) diagram for three stainless steel blade alloys is shown in Fig. 3.

Cyclic stresses are caused by turbine startups and shutdowns (low number of cycles, high

cyclic stresses), by the turbine and blades ramping through critical speeds at which some components are in resonance (high amplitude, high frequency), and by over 15 flow-induced blade excitation mechanisms during normal operation that include:

- Synchronous resonance of the blades at a harmonic of the unit running speed
- Nonuniform flows
- Blade vibration induced from a vibrating rotor or disc
- Self-excitation, such as flutter
- Random excitation—resonance with adjacent blades
- Shock waves in the transonic flow region and shock wave—condensation interaction
- Wrong incidence flow angle and flow separation

There are pronounced thermodynamic effects that cause the concentration of impurities at surfaces and turbine component corrosion. They are most frequent where the metal surface temperature is slightly above the saturation temperature of steam. For the low-pressure fossil utility turbines, this usually occurs on the L-1 blades and on various surfaces of the last two discs. It is one of the reasons the L-1 blades in fossil utility turbines have higher failure rates than any other blade row. Another reason for the high L-1 blade failure rate is the effects of transonic flow (shock waves) and an interaction of the shock waves with the Wilson (delayed droplet nucleation) line (start of condensation; periodic destruction of the Wilson line), resulting in high vibratory stresses (Ref 10, 52, 62–65).

Stress corrosion of low-pressure turbine discs is specifically distributed for each type of turbine and each disc location, indicating a correlation with surface stress, temperature, and steam conditions (Fig. 1) (Ref 1–3, 13–15, 48, 49). This correlation is often related to the impurity concentration by evaporation of moisture. The tendency toward cracking increases with yield strength, stress, and operating temperature. Figure 4 shows massive SCC, caused by high concentration of NaOH in steam, that was discovered during a routine inspection. Figure 5 illustrates the stress-corrosion behavior of NiCrMoV disc steel in “good” water and steam. The effects that yield strength and temperature have on the average crack growth rate of NiCrMoV disc steels are shown in Fig. 6.

There have been catastrophic failures of shrunk-on discs caused by SCC from the keyways, and hundreds of discs have been redesigned and replaced (Ref 1–7, 9, 13, 17–21). This problem was solved by eliminating the keyways and replacing discs with the lower-yield-strength material, typically less than 900 MPa (130 ksi). The current generic problem is SCC of blade attachments in both fossil and nuclear LP turbines (Ref 1–3, 14, 15).

Corrosion of other turbine parts is due to one or more of the same causes described previously (Table 1). There is a strong SCC/low-cycle

fatigue interaction in many turbine components (well recognized in piping) that may be important in stationary blade, bolt, expansion bellows, and turbine cylinder failures. The highest incidence of turbine bolting failures has been in high- and intermediate-pressure cylinders and nozzle blocks, most of it due to the presence of

NaOH. Stress-corrosion cracking of expansion bellows in steam pipes was a problem in fossil units with high concentrations of NaOH (Ref 26). To find the true causes of corrosion, it is essential to analyze the local temperature, pressure, chemistry, moisture velocity, and stress and material conditions.

Fig. 1 Medium-sized utility turbine with locations of corrosion and erosion of steam turbine components. P, pitting; CF, corrosion fatigue; SCC, stress-corrosion cracking; C, crevice corrosion; G, galvanic corrosion; E, erosion; E-C, erosion-corrosion; SPE, solid-particle erosion

Table 1 Corrosion mechanisms in steam turbine components

Component	Material	Corrosion mechanisms(a)
Rotor	Forged Cr-Mo-V or Ni-Cr-Mo-V low-alloy steel	P, SCC, CF, E
Shell	Cast carbon or Cr-Mo-V low-alloy steel, fabricated carbon steel for low-pressure turbines	SCC, E-C
Discs, bucket wheels	Forged Cr-Mo-V, Ni-Cr-Mo-V or Ni-Cr-Mo low-alloy steel, 12Cr weld repair	P, SCC, CF, E-C
Dovetail pins	Cr-Mo low-alloy steels; 5CrMoV, similar to ASTM A681 grade H-11	SCC
Blades, buckets	12Cr stainless steels, 15-5PH, 17-4PH, Ti6-4, PH13-8Mo, Fe-26Cr-2Mo	P, CF, SCC, E
Bucket tie wires	12Cr stainless steels (ferritic and martensitic)	SCC, P, CF
Shrouds, bucket covers	12Cr stainless steels, 15-5PH, 17-4PH, Ti6-4, PH13-8Mo, Fe-26Cr-2Mo	P, SCC
Stationary blades	Type 304 stainless steel, other stainless steels	SCC, SCC-LCF
Expansion bellows	Types 321 or 304 stainless steels, Inconel 600	SCC, SCC-LCF
Erosion shields	Weld-deposited or soldered Stellite type 6B; hardened blade materials	SCC, E
Bolts	Incoloy 901, Refractalloy 25, Pyromet 860, ...	SCC, SCC-LCF
Wet-steam piping	Carbon steel	E-C
Valve bushings and stems	13Cr-Mo and other stainless steels	P, OX

(a) P, pitting; SCC, stress-corrosion cracking; CF, corrosion fatigue; E, erosion; E-C, erosion-corrosion; LCF, low-cycle fatigue; OX, oxidation in steam. General corrosion is experienced by all carbon and low-alloy steel components. Solid-particle erosion is experienced in high-pressure and intermediate-pressure inlets (nozzle blocks, stationary and rotating blades, and valves). It is caused by exfoliation of steam-grown oxides in superheater tubes and in steam pipes.

Pitting (Ref 1–3, 9, 10) is often the initiating corrosion mechanism for SCC and CF. Pit growth seems to decrease with time (parabolic under constant environmental conditions), and pitting is often much faster during unprotected layup (maintenance shut-down) than during normal operation. The main environmental factor causing pitting is the high concentration of chloride in steam and deposits; however, other chemicals can also cause pitting. The presence of pits significantly reduces fatigue strength of turbine materials (Ref 9).

Erosion-corrosion (also called flow-accelerated corrosion) is most pronounced in carbon steel pipes with high-velocity turbulent flow and low-pH moisture containing high concentrations of CO_2 or other acid-forming anions (Ref 2, 27, 28, 30–33). In fossil units, LP extraction pipes can suffer severe erosion-corrosion.

Water droplet and solid-particle erosion (Ref 24, 28, 29) are not believed to be related to corrosion; however, some studies have shown that water droplet erosion is accelerated by the presence of corrosive impurities. Water droplet erosion can initiate fatigue failures of blades by causing surface notches and even changing resonant frequencies of vibration. There have been fatigue failures of last row blade airfoils initiated by water droplet erosion of the trailing edges caused by reversed wet-steam flow during low-load operation or by excessive use of hood sprays.

Turbine Materials

There is little worldwide variation in materials for blades, discs, rotors, and turbine cylinders,

and only a few major changes have been introduced in the last two decades (Ref 2, 6). These materials are listed in Table 1. Titanium alloy blades are slowly being introduced for the last low-pressure stages. Also, improved melting practices, control of inclusions and tramp elements, and weld repair techniques are being used for discs and rotors.

Considering the typical design life of 25 to 40 years and the relatively high stresses, turbine materials perform remarkably well. Turbine steels are susceptible to SCC and CF in numerous environments, such as caustic, chlorides, hydrogen, carbonate-bicarbonate, carbonate- CO_2 , acids, and, at higher stresses and strength levels, pure water and steam (Ref 2, 6, 13–23).

No turbine can permanently tolerate concentrated caustic, sodium chloride (NaCl), or acids. Under such conditions, disc and rotor materials would crack by SCC in a few hundred hours at stresses as low as 10% of the yield strength (Ref 1–21). Chromium steel (12% Cr) blades may tolerate NaOH but would pit and crack by CF at very low vibratory stresses (as low as 6.9 MPa, or 1 ksi) in many other corrodents. With high concentrations of impurities for long periods of time, there would always be a weak link in the turbine or within the power cycle that would fail prematurely. Although titanium could be used for blades and would tolerate most of the impurities (except hydroxides), corrosion-resistant materials for the large forgings of rotors and discs are difficult to find because of the cost, forgeability, banding of alloying elements and impurities, and other problems. Plating and surface coatings appear to be only marginal temporary solutions.

In addition to the susceptibility to localized corrosion in concentrated impurities, the low-alloy and carbon steels used extensively in steam turbines have rather narrow ranges of passivity (Ref 32, 33). This makes these steels vulnerable

Fig. 2 Corrosion fatigue of an L-1 blade airfoil. Courtesy of O. Jonas, Jonas, Inc.

Fig. 3 Corrosion fatigue (Goodman) diagram for three stainless steel blading alloys in various environments. Based on 10^8 cycles to failure at 60 Hz. Source: Ref 23

Fig. 4 Massive stress-corrosion cracking of L-1 disc caused by high concentration of NaOH in steam. Courtesy of O. Jonas, Jonas, Inc.

to pH and oxygen excursions and consequent pitting and other forms of localized corrosion during operation and layup. In chloride solutions, the pH region for passivation becomes even narrower. The material properties needed for designing against corrosion and for failure analysis and evaluation of residual life include fracture toughness (K_{IC}), stress-corrosion threshold stress (σ_{SCC}), threshold stress intensity (K_{ISCC}), crack propagation rate ($(da/dt)_{SCC}$), CF limit, CF threshold stress intensity (ΔK_{th}), CF crack propagation rate (da/dN), pitting rate, and a

pit depth limit, all for a range of temperatures and environments (Ref 1, 2, 24, 32, 33).

Environment

Normally, utility turbine steam is very pure, with the total concentration of impurities less than 50 ppb and the limit for Na, Cl^- , SO_4^{2-} , Fe, and Cu in the 3 to 5 ppb range (Ref 39–45). The normal limit for cation conductivity of

condensed steam is 0.1 to 0.3 $\mu S/cm$. Corrosive impurities are transported into the turbine steam from the preboiler cycle (feedwater and attemperating water) and the boiler as a total (mechanical plus vaporous) carryover. Their major sources include condenser leaks, air in-leakage, makeup water, and improperly operated condensate polishers. Water treatment chemicals, such as NaOH, used for boiler water treatment and amines, oxygen scavengers, dispersants, and chelants can also generate corrosive conditions in the turbine (Ref 50–55). The organics generate acidic conditions by decomposition and formation of acids. The turbine environment is controlled through a control of impurity ingress and various feedwater, boiler water, and steam chemistry limits (Ref 39–46). The corrosiveness of the steam turbine environments (on the surface, at temperature) is caused by one or more of the following:

- Concentration of impurities from low part per billion levels in steam to percent levels on turbine surfaces and the formation of concentrated aqueous solutions (concentration by deposition or evaporation of moisture)
- Insufficient pH control (in both acid and alkaline regions)
- High-velocity, high-turbulence, and low-pH moisture

The situation is illustrated in Fig. 7 and 8, which shows a Mollier diagram with a typical LP turbine steam expansion line, the thermodynamic regions of impurity concentration (NaOH and salts), and the resulting corrosion. The conditions on hot turbine surfaces (in relation to the steam saturation temperature) can shift from the wet-steam region into the salt zone and above by evaporation of moisture. Condensation shock and the transonic flow shock waves can also evaporate moisture and cause impurity concentration. This is why SCC of discs often occurs in the wet-steam regions, and it emphasizes the need to consider local surface temperatures in design and failure analysis. The surfaces may be hot because of heat transfer through the metal (Ref 47, 48) or because of the stagnation temperature effect (zero flow velocity at the surface and conversion of kinetic energy of steam into heat) (Ref 54). Depending on their vapor pressures, near the saturation line, impurities can be present as a dry salt or as a concentrated aqueous solution. In the wet-steam region, they are either diluted by moisture or could concentrate by evaporation on hot surfaces (Fig. 7, 8) (Ref 47, 48).

The steam impurities that are of most concern include chlorides, sulfates, fluorides, carbonates, hydroxides, organic and inorganic acids, oxygen, and CO_2 . Their behavior in turbine steam and deposits is well documented (Ref 1–12, 49–59). There are strong synergistic effects and interactions with metal oxides. However, pure water and wet steam can also cause SCC and CF of turbine blade and disc materials.

Fig. 8 Cross section of a low-pressure turbine illustrating the locations where impurities can concentrate by precipitation, deposition, and by evaporation of moisture to percent concentrations, thus becoming very corrosive. Courtesy of O. Jonas, Jonas, Inc.

In addition to corrosion during operation, turbines can corrode during:

- Manufacture (machining fluids and lubricants)
- Storage (airborne impurities and preservatives)
- Erection (airborne impurities, preservatives, and cleaning fluids)
- Chemical cleaning of boiler (storage of acid in condenser hotwells)
- Nondestructive testing (cleaning and testing fluids)
- Layup (deposits plus humid air)

Many of the aforementioned substances may contain high concentration of sulfur and chlorine, which could form acids on decomposition. Decomposition of typical organics—for example, carbon tetrachloride (CCl_4)—occurs above 150°C (300°F). Therefore, the composition of all of these substances should be controlled (maximum of 50 to 100 ppm sulfur and 50 to 100 ppm chlorine has been recommended), and most of them should be removed before operation. Molybdenum disulfide (MoS_2) has been implicated as a stress corrodent in power system applications (Ref 1, 2, 60, 61).

Layup corrosion increases rapidly when the relative humidity of the air reaches approximately 60%. When deposits are present, layup corrosion can be in the form of pitting or SCC.

Design

Design disciplines that affect turbine corrosion can be separated into four parts:

- Mechanical design (stresses, stress concentrations, and stress intensity, or K_I)
- Heat transfer (surface temperatures and heated crevices)
- Flow and thermodynamics (moisture velocity, location of the salt zone, stagnation temperature, and interaction of shock wave with condensation, that is, the Wilson line)
- Physical shape (crevices, obstacles to flow, and surface finish)

The various aspects of design against environment-induced cracking are well documented (Ref 1–12, 18–21, 24, 34), but only a few of these references deal with the complexity of the problem (Ref 18, 20). Probabilistic approaches are discussed in Ref 34. Problems with such approaches include the lack of a large number of statistical data on corrosion properties of materials, service stresses, and environments. The mechanical design concepts for avoiding turbine corrosion should include evaluation of safety factors against σ_{SCC} , K_{ISCC} , $(da/dt)_{\text{SCC}}$ (Fig. 5), (da/dN) , ΔK_{th} , CF limit, pitting rate, and a pit depth limit.

True residual stresses (welding, overspeed effects) should also be considered. Implementation of the aforementioned concepts requires that

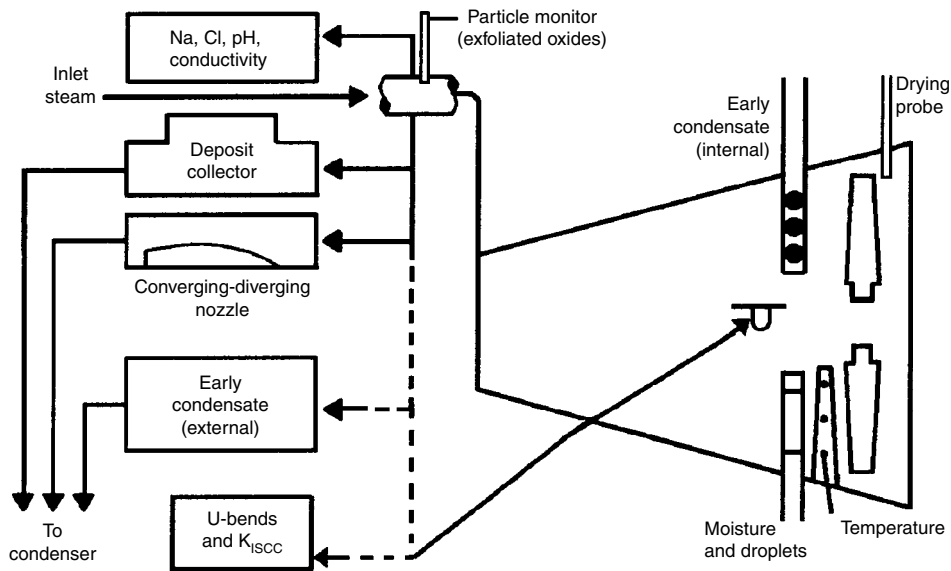

Fig. 9 Low-pressure turbine troubleshooting instrumentation can identify specific corrosive conditions. K_{ISCC} , threshold stress intensity. Courtesy of O. Jonas, Jonas, Inc.

corrosion testing generates quantitative data to be used by the designer.

Solutions to Corrosion Problems

Control of the steam and surface chemistry to minimize turbine corrosion includes (Ref 2, 5, 9, 10, 39–46):

- Decreasing concentration of corrosive impurities in makeup and feedwater, low air inleakage and condenser leakage, and so on
- Oxygenated water treatment for once-through fossil boiler units for excellent feedwater chemistry and clean boilers
- Layup protection
- Turbine washing after chemical upsets to remove deposited impurities
- Reduction or elimination of copper and its oxides and their synergistic corrosion effects by reducing oxygen concentration, operating with a reducing (negative oxidation-reduction potential) environment and a low ammonia concentration, or by replacing copper alloys with steel or titanium

Design and material improvements that reduce turbine corrosion include (Ref 2, 6, 18, 24, 32, 33):

- Welded rotors, large integral rotors, and discs without keyways—eliminate high stress concentrations due to disc keyways
- Replacement of higher-strength NiCrMoV discs with lower-strength (yield < 900 MPa, or 130 ksi) discs and avoiding high-strength blades
- Repair welding of discs and rotors, also with 12% Cr stainless steel weld metal
- Mixed-tuned blade rows to reduce random excitation

- Free-standing and integrally shrouded LP blades without tenon crevices and with lower stresses, as well as frictional damping
- Titanium LP blades—corrosion resistant in turbine environments except for NaOH
- Lower stress and stress concentrations—increasing resistance to SCC and CF
- Flow path design using computerized flow dynamics and viscous flow—lower flow-induced vibration, which reduces susceptibility to CF
- Curved (banana) stationary blades, which reduce nozzle-passing excitation
- New materials for blade pins and bolting that are resistant against SCC
- Flow guides and double-ply expansion bellows—reduce impurity concentration, better SCC resistance
- Moisture extraction to improve efficiency and reduce erosion-corrosion and water droplet erosion, as well as use of alloy steels to reduce flow-accelerated corrosion

Monitoring

The field monitoring equipment shown in Fig. 9 can be used to diagnose and prevent many common LP turbine corrosion and deposition problems (Ref 68). In addition, there are monitors available to detect vibration and provide vibration signatures of the whole machine, blade and rotor cracking, steam leaks, air inleakage, rotor position, and wear of bearings.

Further Study

It is estimated by the author that 70% of knowledge to solve and prevent corrosion problems in steam turbines is available. The

percentage of available knowledge for understanding the effects of stress and environment is much lower, approximately 40%. The knowledge that is missing or needs improvement includes:

- Interaction of SCC and CF
- Threshold stress required to initiate SCC in blade attachments
- Effects of steep geometry (stress concentrations and size) on SCC and CF. The steep is the disc rim blade attachment that matches the blade root (Fig. 4).
- Effects of overloads during heater box and overspeed tests on stress redistribution and SCC in steeples, blade roots, and disc keyways
- Effectiveness of grinding out SCC and CF cracks as a corrective measure
- Effects of organic water treatment chemicals, boric acid, and organic impurities on composition of water droplets, SCC, CF, and pitting
- Effects of electrical charges carried by water droplets on corrosion
- Effects of galvanic coupling of dissimilar materials, such as the blade-steep materials, on corrosion
- Effects of residues of preservatives and anaerobic adhesives on SCC, CF, and pitting of blade attachments
- Effects of blade trailing edge erosion on cracking
- Accelerated stress-corrosion testing
- Effects of variable amplitude loading on CF crack initiation and propagation
- Effects of water droplet pH and composition on erosion, and how to predict erosion
- Existence of Wilson delayed droplet nucleation zone in turbines
- Effects of shot peening to reduce stresses, SCC, and CF of blade steeples and blades
- Understanding the basic mechanisms of stress corrosion, CF, fatigue, and stress-induced pitting

Fireside Corrosion in Coal- and Oil-Fired Boilers

Steven C. Kung, The Babcock & Wilcox Company

THE PRESENCE OF CERTAIN IMPURITIES in coal and oil is responsible for the majority of fireside corrosion experienced in utility boilers. In coal, the primary impurities are sulfur, alkali metals, and chlorine. The most detrimental impurities in fuel oil are vanadium, sodium, sulfur, and chlorine. During combustion, various species containing these impurity elements are produced in the form of vapors and condensed phases. For example, the combustion products from sulfur are predominately SO_2 or H_2S in the gas phase, depending on the stoichiometry of the air/fuel mixture. Vapor species such as alkali sulfates, alkali vanadates, and vanadium sulfates are also formed and subsequently condense on the boiler tubes where the temperatures are lower. The lower metal temperatures inevitably allow continuing accumulation of the deposit, thus creating local environments on the tubes that are significantly different from the bulk of the combustion products.

In general, fireside corrosion in boilers can be loosely divided into two categories by location (i.e., waterwall corrosion in the lower furnace and fuel ash corrosion of superheaters and reheaters in the upper furnace). Different corrosion mechanisms operate on these tube surfaces, as dictated by the local chemistry of combustion gases and deposits, the boiler tube compositions, and the gas and metal temperatures.

Waterwall Corrosion

The lower furnace of a coal- or oil-fired boiler is essentially a large enclosed volume where the combustion of fossil fuel, as well as the cooling of the combustion products, takes place. The furnace enclosures are made of water-cooled tubes, generally in a welded membrane construction. In some cases, these enclosures comprise tangential tube construction or closely spaced tubes with an exterior gas-tight seal. By design, the tube wall and membrane surfaces are exposed to the combustion gases on the fireside, while exterior insulation and lagging prevent heat loss and provide personnel safety.

The majority of construction materials used for furnace walls is carbon steel due primarily to its lower cost. The use of low- and medium-alloy steels, characterized by the addition of a small amount of chromium, molybdenum, and other elements for improved mechanical properties, is also common. For example, ASME SA213-T2 (0.5Cr-0.5Mo, UNS K11547), SA213-T11 (1Cr-1Mo, UNS K11597), and SA213-T22 (2.25Cr-1Mo, UNS K21590) are alloy steels widely used in boilers based on their exceptional high-temperature strength and resistance to graphitization.

Conventional Burners. In boilers equipped with conventional burners, severe fireside corrosion on furnace walls is typically found in small areas, mostly adjacent to the burners where high heat flux is encountered. On these tube wall surfaces, a thick scale is produced that often displays circumferential grooving resembling an alligator hide, as illustrated in Fig. 1. The appearance of these grooves is a result of pointed cracks filled with a mixture of iron oxide and iron sulfide corrosion products. Severe corrosion found in the conventional boilers is attributed to localized reducing conditions caused by improper mixing of air and fuel, along with a high local heat flux leading to elevated thermal stress.

Low- NO_x Burners. To significantly reduce nitrogen oxide (NO_x) formation in utility boilers, a number of low- NO_x burner technologies have been developed in the last decade. Although different in design, all low- NO_x burner technologies implement the strategy of staged combustion that creates substoichiometric combustion zones in the lower furnace. As a result, the fuel is only partially oxidized in the primary combustion zone to suppress NO_x formation. The remaining fuel is combusted with additional air supplied through secondary air ports. Under the substoichiometric combustion conditions, sulfur from the fuel exists primarily as hydrogen sulfide (H_2S) in the flue gas and metal sulfides in the ash (Ref 1). When in direct contact with the furnace walls, such reducing and sulfidizing combustion products cause rapid attack of the boiler tubes through sulfidation.

Consequently, many utility boilers retrofitted with low- NO_x burners have experienced accelerated metal wastage on the lower furnace walls. The wastage is most severe in supercritical boilers burning high-sulfur fuel due to higher metal temperatures and H_2S concentrations. However, subcritical units burning low- and medium-sulfur fuel are not totally immune to the problem. The wastage rates of furnace walls are typically up to 0.5 mm/yr (20 mils/yr) in subcritical boilers and 1 to 2 mm/yr (40 to 80 mils/yr) in supercritical units (Ref 2).

Extensive laboratory studies have investigated the effect of low- NO_x corrosion on furnace walls (Ref 1, 3, and 4). Various alloys and coatings

Fig. 1 Surface of a waterwall showing circumferential grooving resembling alligator hide

were exposed to simulated low- NO_x combustion environments in a high-temperature retort. The laboratory environments consisted of 5 to 12% CO , 500 to 5000 ppm H_2S , approximately 5% H_2O , and the balance CO_2 , N_2 , and H_2 . The test temperatures ranged from 260 to 482 °C (500 to 900 °F), typical metal temperatures for waterwalls. From the corrosion data generated from these studies, a corrosion model was developed that can be used to estimate the corrosion rates of waterwall alloys (carbon and low-alloy steels) as a function of metal temperature, H_2S concentration in the flue gas, and chromium content in the alloy (Ref 4). Figure 2 shows an example of the corrosion rates predicted for SA213-T2 under different H_2S concentrations as a function of metal temperature. Accuracy of the corrosion model was validated by comparing the predicted value to the actual corrosion rate of SA213-T2 on a test panel installed in a coal-fired utility boiler (Ref 4, 5). During the test, the metal temperature and gas composition adjacent to the test panel were carefully monitored. For a long-term exposure, good agreement was obtained between the predicted and actual corrosion rates. This corrosion model is applicable for conditions where the corrosion mechanism is dominated by sulfidation due to H_2S vapor in the gas phase.

Additional studies identified the root cause for the extremely high wastage found on the furnace walls of some coal-fired boilers retrofitted with low- NO_x burners. Severe sulfidation attack can occur on these boiler tubes when covered with an FeS-rich ash deposit under oxidizing or alternating oxidizing/reducing combustion gases (Ref 6, 7). The primary source for FeS is pyrite (FeS_2) present in coal as a natural mineral. In boilers equipped with conventional burners, the pyrite is fully oxidized to iron oxide prior to depositing on the boiler tubes. However, during staged combustion for low- NO_x burners, the pyrite is only partially oxidized to FeS before condensing on certain regions of the furnace walls along with unburned carbon. Laboratory studies demonstrated that subsequent exposure of the FeS-rich ash to oxidizing gases can produce elemental sulfur in the deposit at a concentration up to several percent along with H_2S , COS , and CH_3SH . Depending on the partial

pressure of oxygen, the elemental sulfur is formed via:

The physical state of the elemental sulfur produced is determined by the local temperature. Above the boiling point of 444 °C (832 °F), sulfur vaporizes, and at lower temperature liquid sulfur is stable. The formation of elemental sulfur adjacent to the metal surfaces makes the local environment far more corrosive than expected for gas metal attack under reducing conditions where the corrosion is dominated by H_2S .

Following the discovery of this sulfidation mechanism, another corrosion model was developed using the corrosion data generated from laboratory studies (Ref 6). This model focuses on prediction of severe corrosion rates of alloys covered with FeS-rich ash as a function of O_2 and CO concentrations and metal temperature. Figure 3 gives an example of the average and maximum corrosion rates estimated for SA213-T2 as a function of temperature. This corrosion model was also validated by a field study in which a test panel was installed in a coal-fired utility boiler experiencing severe metal wastage on the furnace walls after low- NO_x burner retrofit. For the long-term field exposure, good agreement was observed between the predicted and actual wastage rates (Ref 8).

Chlorine in coal can also play an important role in waterwall corrosion under reducing combustion conditions. The chlorine concentration of coal produced in the United States typically varies from 0.01 to 0.5%, with the majority falling within 0.05 to 0.2%. A concentration of 0.2% or higher is considered high-chlorine coal and 0.05% or lower is low-chlorine coal. During combustion, chlorine is primarily converted to HCl in the gas phase and alkali chloride in the ash. Laboratory and field data indicate that the corrosion rates of carbon and low-alloy steels are not significantly affected by the presence of a

small amount of HCl or alkali chloride from burning low-chlorine coal. However, when the HCl and chloride concentrations are sufficiently high from burning coal containing $\geq 0.2\%$ Cl , sulfidation attack can be accelerated under substoichiometric combustion conditions (Ref 9, 10). It has been proposed that the presence of chloride in the ash in direct contact with the scale can alter the growth mechanism of FeS formed on the boiler tubes, thus allowing rapid outward diffusion of iron through the scale (Ref 11, 12). In extreme cases, iron chloride is formed at the metal/scale interface, which then leads to severe metal loss via vaporization of FeCl_x , a mechanism similar to that found in municipal solid waste boilers. A direct correlation of corrosion rate with the coal chlorine content has been reported by researchers in the United Kingdom, where the chlorine concentration available in coal has increased steadily from 0.35 to 0.65% over the last two decades (Ref 10, 13).

Mechanisms for the formation of iron chloride at the scale/metal interface have been proposed (Ref 13, 14). Chlorine can react with iron to form iron chlorides underneath the scale during boiler operation (Ref 13, 15). The condensation of moisture can also occur during boiler downtime when the ambient temperature falls below the dew point (Ref 12). As a result, water dissolves chlorides in the ash and enters the scale through its pores and cracks. Such a mechanism implies that downtime corrosion can contribute to the overall corrosion wastage observed on the boiler tubes.

Fuel Ash Corrosion

In the upper furnace, fireside corrosion is often found on the superheaters and reheaters, in particular, in the steam outlet sections where the metal temperatures are the highest. The combustion gas is typically oxidizing, containing about 3% excess oxygen. As a result, sulfur is present in the flue gas primarily as SO_2 and SO_3 . The tubes suffering severe wastage are generally covered with a thick layer of ash deposit that becomes partially molten at the metal temperatures. The formation of a molten phase at the tube surfaces allows a "hot corrosion" attack, which causes dissolution and fluxing of the otherwise protective oxide scales formed on the alloys (Ref 16).

Coal ash corrosion was extensively studied in the 1980s and 1990s. In coal-fired boilers, accelerated corrosion is related to the formation of a fused complex sulfate, alkali iron trisulfate ($\text{Na,K}_3\text{Fe(SO}_4)_3$), which exists at a metal temperature of 593 to 732 °C (1100 to 1350 °F). The melting point of synthesized alkali iron trisulfate varies with the Na-to-K ratio, with the lowest temperature of 552 °C (1025 °F) occurring at the ratio of 2/3 (Ref 17). Because the corrosion mechanism requires the formation of a molten phase, variation of the Na-to-K ratio in the coal inevitably affects the corrosivity of the ash. The melting point can be further reduced

Fig. 2 Predicted corrosion rates of SA213-T2 (UNS K11547) alloy steel under different H_2S concentrations as a function of metal temperature

Fig. 3 Maximum and average corrosion rates predicted for SA213-T2 (UNS K11547) alloy steel covered with FeS-rich ash in combustion gas containing 1% O_2 as a function of metal temperature

when additional compounds dissolve in the trisulfate formed in the ash. The complex sulfate has been shown to exhibit an acid-base behavior that can be defined and measured quantitatively by electrochemical probes (Ref 18, 19). This fused salt acts as an effective solvent for protective scales, aggravating the hot corrosion attack.

Coal ash corrosion is found on superheaters and reheaters covered with a deposit that is strongly bonded to the tube surfaces. The deposit consists of at least three distinct layers (Ref 20). The outer layer constitutes the bulk of the deposit and has an elemental composition similar to that of fly ash. This hard and brittle layer is typically porous, allowing the gas species to diffuse through easily. Underneath the outer layer, a white to yellow-colored layer is present. This intermediate layer, often referred to as the "white layer," can melt as low as 538 °C (1000 °F) upon heating in air. This layer is rich in sulfur and alkali metals due to the presence of a complex sulfate that is the essential ingredient for fuel ash corrosion. The inner layer usually is thin and consists of corrosion products produced from oxidation and sulfidation of the base metal.

The greatest metal loss on superheaters and reheaters occurs on the upstream side of the boiler tubes at the 2 and 10 o'clock positions, as illustrated in Fig. 4 (Ref 21). At these locations, the outer ash layer is relatively thin because of gas stream erosion and the gas temperature is high. Consequently, a high heat flux is created locally, which leads to a high metal temperature and thus the formation of a molten intermediate ash layer. The corrosion wastage is less severe at the 12 o'clock position because sufficient thermal insulation is provided by the thicker deposit layer. The metal wastage tapers off to little or none on the back side of the tubes away from the hot gas stream.

The corrosion rate is not a linear function of metal temperature. Instead, a bell-shape curve is often used to describe the behavior of fuel ash corrosion. The relative weight losses of ASME SA213-T22 (2.5% Cr) and 304 stainless steel (18Cr-8Ni, UNS S30400) in a simulated coal-fired combustion environment are shown in Fig. 5. The wastage rates exhibit a sharp increase above the metal temperature of 538 °C (1000 °F), reach the maximum at 677 to 732 °C (1250 to 1350 °F), and decrease rapidly at higher temperatures. Such a corrosion curve derives from the melting temperatures of the complex sulfates as well as the thermodynamic stability of these compounds. In a temperature range from as low as 538 °C (1000 °F) to the maximum, the corrosion mechanism is dominated by the formation of a molten phase in the intermediate ash layer. With the active fuel ash corrosion taking place, the rate increases greatly with the metal temperature. Beyond the maximum, the complex sulfates are no longer stable. As a result, active fuel ash corrosion ceases and the metal loss is significantly reduced.

In oil-fired boilers, vanadium plays the most important role in fuel ash corrosion. During

combustion, vapors of vanadium pentoxide (V_2O_5) and alkali sulfates are formed. These vapors subsequently condense onto the cooler tube surfaces along with other ash constituents. Vanadium pentoxide reacts with alkali sulfates in the deposit to form low-melting temperature alkali vanadate compounds and/or their solutions (Ref 22). Once formed, the molten phase can attack the superheaters and reheaters via the hot corrosion mechanism (Ref 16). Although the concentration of vanadium in fuel oil is relatively low, typically less than 300 ppm, it tends to accumulate on the tube surfaces and can become 80% of the deposit constituents.

Because alkali sulfates play an important role in lowering the liquidus temperature of a deposit, the severity of oil ash corrosion also depends on the sodium and sulfur concentrations in the oil. In general, the corrosion attack is enhanced by increasing the sodium and sulfur contents. Furthermore, chlorine is generally present in fuel oil at a concentration up to 100 ppm. As a result, chloride is commonly found in the oil ash deposit as NaCl. Laboratory studies indicate that the addition of sufficient NaCl to V_2O_5 can increase the corrosion rates of boiler tubes significantly (Ref 23). Surprisingly, adding a low level of HCl to the flue gas has no effect on oil ash corrosion (Ref 24).

Prevention of Fireside Corrosion

Means for addressing fireside corrosion range from fuel additives to changes in boiler operations to changes in tube materials. In the lower furnace where severe corrosion is caused by the presence of reducing/sulfidizing conditions, the problem can sometimes be minimized by adjusting the air and fuel distribution to the burners. Other remedies include air blanketing, burner modifications, and refined specifications on coal fineness. To reduce the amount of impurities introduced to the boilers, fuel switching or blending to lower the overall sulfur and alkali contents is sometimes recommended. Furthermore, a significant amount of sulfur and alkali metals in coal can be removed by coal washing. However, washing does not remove chlorine and can therefore inadvertently amplify the problems associated with chlorine. Of course, modification of any of the boiler operations can lead to a higher cost in plant

Fig. 4 Fuel ash corrosion on superheater and reheater tubes showing the maximum metal loss at the 2 and 10 o'clock positions

operation. Therefore, any benefit gained from the increased tube life must be carefully weighed against the increased cost.

From the material selection perspective, the sulfidation resistance of waterwall alloys has been shown to increase with their chromium content (Ref 3, 4). Tube alloys containing 9 to 12% Cr exhibit satisfactory resistance when exposed to low- NO_x combustion gases. Furthermore, a higher chromium content is needed when the corrosion mechanism involves an FeS-rich deposit along with an oxidizing or alternating reducing/oxidizing environment. Because it is not practical to construct the waterwalls with high chromium content alloy steel or stainless steel tubing, application of a protective clad or coating may be necessary to combat fireside corrosion in the lower furnace.

Various coatings are available for waterwall protection; these can be applied either in the shop or directly in the field. The primary techniques used for field-applied coatings are metal spray and weld overlay. The most common metal spray processes consist of wire arc spray and high-velocity oxyfuel (HVOF). Both spray processes typically achieve a coating layer of high-chromium material 0.4 to 0.75 mm (15 to 30 mils) thick. The arc spray process allows low energy input and can achieve a high spray rate. Consequently, this process is relatively inexpensive and fast. The HVOF process generally produces a denser coating with less oxide inclusion and porosity. Therefore, the HVOF-applied coatings are less permeable to the corrosive gases and can provide better protection to the furnace walls. However, HVOF is more expensive than arc spray. Common alloy powders selected for the sprayed coatings on waterwalls include 309, 310 stainless steel, and 50Ni-50Cr.

Weld overlay produces a coating of high-chromium alloy composition on the tube surfaces at a typical thickness of 1.5 to 2.0 mm (60 to 80 mils). The common materials of selection are alloys 622 (UNS N06022), 625 (UNS N06625), 309 (UNS S30900), and 312 (UNS S31380). These coatings are relatively dense,

Fig. 5 Corrosion rates of chrome (2.5%) ferritic steel, SA213-T22 (UNS K21590), and 18Cr-8Ni stainless steel, type 304 (UNS S30400), exhibiting a bell-shape curve as a function of temperature

impermeable to the combustion gases, and well bonded to the metal substrate. Therefore, the long-term performance of weld overlay is likely to be better than that of metal spray. However, the major drawback of weld overlay is its high cost and sensitivity to coefficient of thermal expansion (CTE) mismatch between the weld metal and substrate. A high CTE mismatch often leads to distortion and cracking of the water-walls.

While the coatings mentioned previously can also be applied in the field or shop, alternative processes lack such flexibility. In particular, coatings applied by laser cladding and diffusion processes must be done in the shop on replacement panels. Following the coating applications, these panels are then installed on the furnace walls in areas where severe corrosion is experienced. Similar to weld overlay, laser cladding can produce a dense and impermeable coating of high-chromium alloy composition. However, because of its low heat input, the laser-clad coating suffers little from chromium dilution caused by interdiffusion with iron in the substrate. The most common alloy compositions applied by laser cladding are alloys 622, 625, and 309. Due to CTE mismatch, distortion of the laser-clad panels can also occur. Therefore, panel straightening is usually required after such coating applications.

Diffusion coatings involve alloying of protective elements, such as chromium, aluminum, and silicon, into the substrate surface. The coating is commonly applied by the pack cementation technique or its derivatives, which involve exposure of the substrate to a pack mix heated to high temperatures under an inert or reducing environment. The pack mix consists of powders of active metal(s), a halide salt activator, and an inert oxide powder as the matrix. For boiler applications, chromizing, which produces a higher chromium concentration at the tube surfaces, is the most widely accepted process. Co-diffusion coatings that introduce two or more protective elements simultaneously, such as chromizing/aluminizing and chromizing/siliconizing, have also been

developed (Ref 25). See the article "Pack Cementation Coatings" in *ASM Handbook*, Volume 13A, 2003.

In the upper furnace of coal-fired utility boilers, where molten ash is the dominant cause of corrosion, different methods have been implemented to protect the superheaters and reheaters. These include the use of heat shields to guard the most vulnerable tubes and the use of soot blowers to minimize the deposit buildup. Fuel switching and blending can also be effective when cost benefit prevails. Other approaches consist of changes to furnace geometry, burner configuration, tube bundle arrangement, and the use of gas tempering. All of these approaches aim at reducing the gas and metal temperatures as well as minimizing the temperature imbalance. In terms of alloy selection, the allowable stress and cost, as well as oxidation and corrosion resistance, determine the materials prescribed for superheaters and reheaters. Whenever possible, the use of carbon steel is always maximized due to its lower cost. However, careful selection of alloy steels and stainless steels is necessary for tube elements where the gas and metal temperatures are the highest.

In units where coal ash corrosion occurs, economical heat-resistant steels, such as 304, are often used in the outlet sections of superheaters and reheaters. For extreme cases found in boilers burning coal containing high sulfur and alkali contents, selection of a higher corrosion-resistant alloy (alloy 800H clad with alloy 671, for example) becomes necessary. The use of sprayed metal coatings and ceramic coatings to combat coal ash corrosion is generally ineffective due to coating spallation, erosion, and rapid deterioration.

The steam outlet temperature of a supercritical boiler is typically designed to be less than 566 °C (1050 °F). However, to further increase plant efficiency and reduce emissions, ultrasupercritical coal-fired utility boilers are being developed. The steam outlet temperature and pressure in the proposed ultrasupercritical units can be as high as 750 °C (1380 °F) and 100 MPa (14.5 ksi), respectively. Aside from having

adequate creep and oxidation resistance, the superheater and reheater materials must withstand the coal ash corrosion that occurs at a rate near the peak of the bell-shape curve (Fig. 5). Under these conditions, few commercially available alloys can meet the stringent requirements. See the article "Corrosion in Supercritical Water—Ultrasupercritical Environments for Power Production" in this Volume for more details on these units.

To select candidate superheater and reheater materials, test loops consisting of various high-performance alloys and coatings were installed in a coal-fired utility boiler burning high-sulfur coal as part of a long-term field study (Ref 26). The test loops were designed to simulate the steam conditions expected in an ultrasupercritical unit. The test results reveal a strong correlation between the corrosion resistance of alloy and its chromium concentration (Fig. 6). Only a chromium content of 40% or greater in the alloy can provide adequate resistance to such coal ash corrosion. An even better correlation is found between the corrosion resistance and the sum of chromium and nickel contents among the alloys investigated (Fig. 7). Such a correlation suggests that the use of high-chromium nickel-base alloys, such as 671 (50Ni-50Cr) and 740 (Ni-25Cr-20Co-Nb-Ti-Al), may be necessary for the superheaters and reheaters of ultrasupercritical boilers (Ref 27).

At present, no alloys are immune to fuel ash corrosion in oil-fired boilers. In general, the higher the chromium content, the more corrosion resistant the alloy is. Therefore, high-chromium alloys and coatings are commonly used in oil-fired boilers to combat the corrosion attack. Ferritic steels are more corrosion resistant to oil ash corrosion than nickel-containing austenitic alloys (Ref 28). Among them, SA213-T9 and SA268-TP410 are most widely used. However, on components such as uncooled tube supports where the metal temperatures are high, the use of a higher-chromium alloy or coating, such as 50Ni-50Cr, is necessary.

Other remedies for oil-fired boilers include reducing the tube metal temperature by the use of

Fig. 6 Maximum coal ash corrosion rates of alloys in ultrasupercritical boilers as a function of chromium concentration. Squares and diamonds are data from different test loops.

Fig. 7 Maximum coal ash corrosion rates of alloys in ultrasupercritical boilers as a function of Cr + Ni concentration. Squares and diamonds are data from different test loops.

a parallel steam flow or decreasing the steam outlet temperature. Operating oil-fired boilers with low excess air can also decrease the metal loss by altering the dominant vanadium compounds formed. At a low partial pressure of oxygen, vanadium exists predominantly as non-corrosive high-melting V_2O_4 instead of corrosive low-melting V_2O_5 . Inhibitors and additives can be used to reduce oil ash corrosion with varying success. MgO is the most effective inhibitor that reacts with vanadium to form a compound having a melting point above the tube metal temperatures (Ref 29). Without the presence of a molten phase, the oil ash corrosion is significantly impeded.

High-Temperature Corrosion in Waste-to-Energy Boilers

George Y. Lai, Consultant

THE COMBUSTION OF MUNICIPAL SOLID WASTE in a waste-to-energy (WTE) boiler for power generation produces a very corrosive environment for the boiler tube materials. Municipal solid waste typically contains plastic materials, textile, leathers, batteries, food waste, and other miscellaneous materials. These constituents are the source of chlorine, sulfur, sodium, potassium, cadmium, zinc, lead, and other heavy metals that form corrosive vapors of various metal chlorides and sulfates during combustion. These chloride and sulfate vapors, along with fly ash, condense and deposit on the cooler surfaces, such as the waterwalls that surround the combustion zone, and heat-exchanger surfaces in the convection path in the upper furnace. Vulnerable heat-exchanger parts in the convection path are screen tubes, superheater tubes, and generating banks. The waterwall, screen tubes, and generating bank tubes are typically made of carbon steels, while superheater tubes are made of carbon steels or chromium-molybdenum steels. The corrosion problems with these boiler tubes in WTE boilers is discussed in detail in Ref 1 to 4, and a review on WTE boilers and their associated corrosion and materials issues is found in Ref 5.

Corrosion Modes

Typical gases and combustion products found in the flue gas stream consist of O_2 , CO_2 , H_2O , SO_2 , HCl , HF , and N_2 . Among these gaseous constituents, SO_2 , HCl , and HF are considered to be corrosive at high temperatures. Reference 4 reports typical ranges of concentrations in mass-burning units as 100 to 200 ppm SO_2 , 400 to 600 ppm HCl , and 5 to 20 ppm HF ; in refuse-derived-fuel units (RDF) 200 to 400 ppm SO_2 , 600 to 800 ppm HCl , and 10 to 30 ppm HF . These levels of SO_2 , HCl , and HF are not likely to be responsible for high wastage rates observed for nickel-base alloy 625 (Ni-22Cr-9Mo-3.5Nb, UNS N06625) in superheaters in some boilers. As shown in Fig. 1, for example, alloy 625 overlay cladding (approximately 2 mm thick) was completely corroded after 15 months of

service in a superheater (Ref 6). Laboratory tests (Ref 7) simulated conditions in N_2 with 10% O_2 , 50 ppm SO_2 with 500 ppm HCl in one environment and with 4% HCl in another environment. Tests were conducted at 593 °C (1100 °F) for 1008 h. This temperature is much higher than superheater metal temperatures in WTE boilers. It was found that alloy 625 showed very little corrosion attack in both 500 ppm and 4% HCl environments. The extrapolated corrosion rates were 2.79 $\mu m/yr$ (0.1 mils/yr) and 15.75 $\mu m/yr$ (0.6 mils/yr) in 500 ppm HCl and 4% HCl environments, respectively. The level of 4% HCl is significantly higher than the level expected in the combustion of municipal waste. From these data, it can be concluded that gaseous HCl plays no significant role in causing significant wastage rates observed for both waterwalls and superheaters.

The metal chloride vapors or deposits that are not usually measured in the combustion flue gas stream could be responsible for causing high corrosion rates for metallic components. Some of the metal chlorides exhibit high vapor pressures.

Fig. 1 The overlay cladding, approximately 2 mm (80 mils) thick of alloy 625 (UNS N06625) overlay superheater tube, was corroded away in 15 months in a waste-to-energy boiler.

For example, $ZnCl_2$ exhibits 10 Pa (10^{-4} atm) of vapor pressure when the temperature reaches 349 °C (660 °F). This vapor pressure is generally considered to be high enough to cause high-temperature corrosion. Studies of the corrosion of alloys by $ZnCl_2$ vapor at 540 °C (1000 °F) found alloy 625 suffering an extrapolated corrosion rate of 3.07 mm/yr (121 mils/yr) (Ref 8). Some of the salt vapor might have deposited on the test specimen as well in the test. Thus, the corrosion attack could be due to both $ZnCl_2$ vapor and liquid deposit. Nevertheless, the extrapolated corrosion rate was in the same order of magnitude as the wastage rates observed for alloy 625 cladding in coextruded composite or weld overlay superheater tubes in some aggressive WTE boilers (Ref 6, 9). Many chlorides exhibit low melting points. Figure 2 shows the

Fig. 2 Melting points of various metal chlorides including eutectics and sulfur-containing compounds that might be present in waste-to-energy combustion environments (Ref 10)

melting points of those metal chlorides including eutectics and sulfur-containing products that might be present in WTE combustion environments (Ref 10).

Analyses using scanning electron microscopy with energy dispersive x-ray spectroscopy (SEM/EDS) performed on the ash deposits and corrosion products formed on the waterwall tube or superheater tube showed the presence of chlorine, sodium, potassium, zinc, lead, and other elements. The corrosion products at the corrosion front were found to contain chlorine, sodium, potassium, zinc, and lead, as well as the elements from the tube metal. Figure 3 shows an example of one analysis on the deposits and corrosion products formed on a steel tube in the waterwall of a WTE boiler (Ref 6). The corrosion products at the corrosion front (location numbers 5, 6, and 7 in Fig. 3) were found to contain iron, chlorine, zinc, cadmium, and sodium. It implies that zinc, cadmium, and sodium along with chlorine in this case were participating in the corrosion of the steel tube. Thus, it is believed that the molten chloride salts involving zinc, lead, sodium, potassium, and other metals are primarily responsible for corrosion attack on the waterwall. In the superheater area, because of higher temperatures, some chlorides, such as ZnCl_2 , may exhibit high vapor pressures. In this case, corrosion attack may involve chloride attack by both liquid and vapor phases.

Location	Composition, %

Corrosion Protection and Alloy Performance

The discussion on the corrosion protection and alloy performance will focus on two main areas of the boiler: furnace water walls and super heaters.

Furnace Waterwalls. Due to aggressive environments in both the lower furnace and the convection path, the conventional tube materials, such as carbon steels and chromium-molybdenum steels, for waterwalls and superheaters require some sort of corrosion protection. The current prevailing method of protection for the furnace waterwalls is the use of alloy 625 overlay cladding applied by automatic gas metal arc welding (GMAW) process (Ref 6, 11). The overlay cladding is typically performed on-site in the boiler. Figure 4 shows a schematic for the application of the overlay cladding for the waterwall, which consists of membranes and tubes. The performance of the alloy 625 overlay has been found to be satisfactory in both mass-burning and RDF units. Corrosion attack tends to be of pitting type, as shown in Fig. 5. The area that has suffered corrosion attack can be readily repaired by overlay welding. This repair is performed by first grinding out the corroded or pitted area, and then overlay welding.

In general, the tube metal wastage rate for alloy 625 overlay on the waterwalls has been observed to be about 0.13 mm/yr (5 mils/yr) for many boilers (Ref 12). Localized or pitting corrosion attack with higher corrosion rates has also been encountered. These 625 overlays in WTE boilers in general exhibit a dilution of 10% or less. This means about 10% or less Fe is observed in the alloy 625 overlay, which typically originates as < 1.0% Fe in the weld wire. It is believed that excessive dilution (15 to 20% Fe) might

significantly enhance the wastage rate. High iron content in the overlay, which results from high dilution, could increase the probability of forming low-melting-point iron-containing chlorides, such as FeCl_2 and/or FeCl_3 and their eutectics, thus promoting higher wastage rates.

Superheaters. One of the very common corrosion protection methods for superheaters is the use of bimetallic tubes with alloy 625 cladding on the outer diameter of the carbon or chromium-molybdenum steel tube. The 625 cladding can be fabricated by overlay welding (Ref 13) or by coextrusion manufacturing (Ref 9). Figure 6 shows an example where alloy 625 overlay tubes have been performing well in the superheater in a WTE boiler (Ref 6). There was no evidence of corrosion attack after 4½ years of service in a superheater producing 405 °C (761 °F) and 42 bars (609 psi) superheated steam. Table 1 summarizes the comparative performance between bare carbon steel tube and alloy 625 overlay tube in a side-by-side test in another boiler. The superheated steam temperature and pressure for this boiler were 399 °C (750 °F) and 52 bars (750 psi), respectively. Wastage rates were observed to be about 2.8 mm/yr (110 mils/yr) for carbon steel and 0.46 mm/yr (18.3 mils/yr) for alloy 625 overlay (Ref 6). Based on these data, the replacement intervals for carbon steel tubes are expected to be 1.4 years and alloy 625 overlay tubes 5.8 years in this boiler, which is a service life improvement of slightly more than fourfold. For some boilers, the environments have been found to be much more aggressive such that alloy 625 cladding in either coextruded tubes or weld overlay tubes exhibited wastage rates exceeding 1.27 mm/yr (50 mil/yr) (Ref 9, 12). The overlays made from other nickel alloys, such as alloy 622 (Ni-21Cr-14Mo-3W), C276 (Ni-16Cr-16Mo-4W, UNS N10276), 52 (Ni-30Cr-10Fe, UNS N06052) and

	mm/yr	mils/yr
Carbon steel	2.8	110
625 overlay	0.46	18.3

Source: Ref 6

72 (Ni-44Cr, UNS N06072), were tested and found to be not as good as the alloy 625 overlay (Ref 12).

The wastage rates observed for alloy 625 cladding in either coextruded tubes or weld overlay tubes were found to range from less than 0.25 to more than 1.25 mm/y (less than 10 to more than 50 mils/yr) depending on the boiler (Ref 9, 12). There have been significant variations in wastage rates from boiler to boiler. The possible reason could be that the superheater metal temperatures are much higher than those of waterwalls. This may make the superheater much more sensitive to waste constituents, particularly the concentrations of chlorine, zinc, lead, and other heavy metals. Other factors that may also be important in affecting the wastage rates include boiler design, temperatures and velocities (also local velocities) of the flue gas stream entering into the superheater bundle, and steam temperature and pressure.

Another common protection method is the use of tube shields, which are typically made of type 309 (UNS S30900), 310 (UNS S31000), 253MA (UNS S30815) stainless steel, or other austenitic alloys. Figure 7 shows carbon steel superheater tubes protected by metallic tube shields awaiting installation at a WTE plant. The tube shields are generally exposed to the temperatures as high as those of flue gas stream entering into the superheater tube bundle, which can vary from 650 to 900 °C (1200 to 1650 °F). As a result, the tube shields typically suffer chloride attack and sulfidation attack. Furthermore, the shields are typically attached to the tube by mechanical clamps and fillet welds. In addition to

Fig. 6 Overview (left) and close-up view (right) of alloy 625 overlay tubes after 4½ years of service in a superheater in a WTE boiler. Weld bead ripples are still clearly visible.

Fig. 7 Carbon steel superheater tubes protected by metallic tube shields awaiting installation at one waste-to-energy plant

high-temperature corrosion, the shields also suffer warping, distortion, and creep damage. Common problems associated with tube shields include:

- Accumulation of ash/salt deposits behind the shields causing accelerated corrosion on the tube
- Impeding gas flow by fallen shields

Tube shields are generally considered to be a “sacrificial” part and are to be replaced regularly during the plant maintenance shutdown in order to avoid the aforementioned problems.

Corrosion of Industrial Gas Turbines

Henry L. Bernstein and Ronald L. McAlpin, Gas Turbine Materials Associates

INDUSTRIAL GAS TURBINES are used in a variety of industries to generate electricity, produce steam, and provide mechanical shaft power. The utility industry often refers to them as combustion turbines so as to distinguish them from steam turbines (since both use gases to generate energy). They are also used on ships for propulsion and to generate electricity, in which case they are called marine gas turbines.

The corrosion issues for industrial gas turbines are similar for all applications and depend more on the quality of the fuel, air, and water used in the engine than on the specific industrial application. In the compressor section, aqueous corrosion is the principal concern. In the combustor and turbine sections, high-temperature environmental attack in the form of high-temperature oxidation and hot corrosion are the most important.

Corrosion in the Compressor Section

Compressor blades and vanes are usually made from martensitic or precipitation-hardening stainless steels and can either be coated or bare. Compressor disks, and many turbine disks as well, are made from low-alloy steels and, sometimes, martensitic stainless steels. Humidity in the atmosphere can be sufficiently high that water condenses on the forward compressor components during operation. Inlet air water fogging and evaporative cooling are sometimes used to increase power, especially in newer installations. In addition, water vapor can collect in compressor and turbine sections of peaking units that are idle. Some utilities heat or dehumidify their turbines when they are not in use to avoid this problem or cover the inlet and/or outlet to prevent air circulation through the turbine.

Forms of Corrosion. General corrosion and pitting can result from the accumulation of water on compressor blades, stators and disks. If corrosion is extensive, parts may need to be replaced. Pitting on blades and vanes can increase the likelihood of fatigue crack initiation. Corrosion fatigue can dramatically reduce the life of steels used for compressor blades, as shown in Fig. 1.

Fouling can result from carryover of fines from the inlet air filters as well as the buildup of

corrosion products. Fouling and corrosion can be exacerbating problems, as the presence of deposits and moisture increases the likelihood of pitting in the blade alloys. Fouling of compressor blades also reduces the efficiency of the compressor, increasing the heat rate and reducing the output of the engine. Corrosion problems are compounded when aggressive environments are present, such as salt air or airborne contaminants.

Corrosion from condensation during outages is often encountered in low-alloy steel disks used in the hot section of the turbines. Exposure to moisture during outage periods can increase the fretting wear of the blade attachments on the turbine disks.

Periodic cleaning of the compressor can restore much, but not all, of the efficiency and power lost because of fouling (Ref 2). On older units with uncooled turbine blades and vanes, abrasive blasting using crushed nutshell or other media is sometimes used. Water washing is the primary method of compressor cleaning in most industrial gas turbines and can be performed either off-line or online. Online washing usually employs just water, and allows operators of turbines used in intermediate- or base-load service to clean without interrupting operation. Care must be exercised with online washing because of the risk of water-droplet erosion to the compressor blades. Original equipment manufacturers (OEMs) may limit the frequency and duration of online water washing cycles. Off-line water washing solutions can include detergents, dispersants, and organic solvents, with detergents being the most common due to environmental considerations. Control of the wash-water

Fig. 1 Reduction of fatigue life of a martensitic stainless steel in a saltwater environment. Source: Adapted from Ref 1

quality is very important to prevent corrosion, especially for online washing. (Water containing small amounts of sodium or potassium can cause hot corrosion in the turbine section of the engine.) Thorough rinsing after the off-line washing is required to remove all detergent.

Off-line water washing provides a more thorough cleaning of the compressor. Online washing is only effective on the first few compressor stages because the water evaporates as the air is heated. The effectiveness and benefits of online washing are debated and probably depend on a variety of factors, including the location of the site, air filtration, frequency of washing, and the design of the washing system.

Coating Systems. Nickel-cadmium coatings can be used to protect the blades and vanes from corrosion and erosion and to improve the surface finish and compressor efficiency. This coating can pit in acidic conditions and can degrade by cadmium vaporization in the latter compressor stages. Since the nickel-cadmium coating is cathodic to the base metal, it can increase the rate of corrosion at pits and coating defects. Because cadmium is toxic, nickel-cadmium coatings have been discontinued.

Current (2006) coating systems consist of metallic-ceramic coatings, an example of which is shown in Fig. 2. These coatings are used on the

Fig. 2 Compressor coating. The coating is composed of an aluminum-filled inorganic phosphate with a polytetrafluoroethylene (PTFE) layer on top. Beneath the PTFE layer is an ion-reactive primer that inhibits corrosion, which otherwise would cause delamination of this top layer. As-polished. Courtesy of Sermatech International

blades, vanes, and disks. These coatings are anodic, which will limit base-metal corrosion even when defects or erosion damage is present. The base coat is protected by a seal coat, which can also be chemically active to promote passivation of the galvanic layer. Seal coats can include fillers and pigments for improved toughness or can be smooth to improve aerodynamics. Organic seal coats can be used to improve surface slickness, limit fouling tendency, and facilitate cleaning of the blades for improved efficiency. Organic coatings are typically limited to 260 °C (500 °F) operation.

Corrosion in the Combustor and Turbine Sections

The materials commonly found in the combustor and turbine sections are superalloys and stainless steels. Nickel-base superalloys are typically used for combustor liners, transitions, blades, vanes, shrouds, and sometimes disks because of their high strength at high temperatures. Cobalt-base superalloys are typically used for vanes because of their good resistance to hot corrosion and good weldability. Iron-base superalloys are typically used for disks and lower-temperature blades, vanes, and shrouds. Stainless steels, both austenitic and martensitic, are used for lower-temperature static parts, fuel nozzles, and sometimes disks. Low-alloy steels are sometimes used for disks. While corrosion issues can occur for all of these materials and components, these issues are most often encountered with the blades and vanes.

When the alloys do not have sufficient resistance to corrosion by themselves, high-temperature coatings are used. These coatings are a separate metallurgical system that is applied over the surface of the part. These coatings are discussed in a separate section of this article.

The main corrosion issues in the combustor and turbine sections are high-temperature environmental attack in the form of high-temperature oxidation and hot corrosion. Hot corrosion is usually subdivided into two types—high-temperature hot corrosion (type I) and low-temperature hot corrosion (type II)—although additional categories have been used. The

approximate temperature regimes over which these forms of attack occur, and their severity, are shown in Fig. 3.

Further information about high-temperature environmental attack and high-temperature coatings can be found in the article “Design for Oxidation” in Volume 20 of the *ASM Handbook*, in Part 4 of the book, *Superalloys II* (Ref 3), and in review papers (Ref 4, 5). There is a voluminous and ever-expanding collection of literature in this area, and these sources contain references to some of this literature. While much of the basic knowledge of this area has been well established, there are still aspects that are not well understood.

High-Temperature Oxidation

High-temperature oxidation is the oxidation of the metal and its alloying elements. It results in

the formation of an external oxide scale that may or may not be protective. A protective scale grows slowly (due to a slow rate of diffusion of metal and oxygen ions through the scale) and is adherent to the metal substrate. For non-protective scales, an internally oxidized region and an alloy-depleted layer occur beneath the metal surface. This region often contains nitrides as well as oxides. Micrographs of external and internal oxidation are shown in Fig. 4. High-temperature oxidation accelerates with higher temperatures.

High-temperature oxidation is typically not a major problem in industrial gas turbines. It usually becomes a problem when temperatures are hotter than expected, due to the prediction of too low of a temperature during the design process, or the operation of the engines at too high of a temperature. Sometimes it is a problem because the base metal or coating selected has insufficient oxidation resistance.

High-temperature oxidation can usually be controlled by the use of base metals having sufficient oxidation resistance by themselves, or by the use of a protective coating. (It should be noted that the base metal has to have sufficient resistance to oxidation by itself so that if portions of the coating are lost, the component can successfully operate to the next inspection interval.) Occasionally, the temperature of the component is so high that additional cooling of the component is needed and/or a thermal barrier coating is needed to reduce the metal temperature.

Hot Corrosion

Hot corrosion can be very destructive, as shown in Fig. 5.

High-temperature hot corrosion, also called type I hot corrosion, occurs at metal temperatures between 815 and 955 °C (1500 and

Fig. 3 Regimes of high-temperature attack. Temperatures are approximate.

The alloy-depleted layer includes the internally oxidized layer. The base metal is shown at B. Kallings etch

Fig. 5 Severe attack of an aeroderivative gas turbine blade by hot corrosion

1750 °F) when sulfur is present along with potassium or sodium. It is most severe at temperatures between 845 and 925 °C (1550 and 1700 °F). High-temperature hot corrosion is caused by the formation of alkali metal salts, such as sodium sulfate (Na_2SO_4) and potassium sulfate (K_2SO_4), which melt and form a liquid on the surface. This molten salt attacks the oxide scale, destroying the protection normally afforded by this scale. Once the oxide scale is breached, sulfidation and oxidation of the metal occurs, which results in the rapid destruction of the metal surface.

A micrograph of high-temperature hot corrosion is shown in Fig. 6. A broad, relatively uniform attack is present that consists of sulfides at the tip of the attack and internal oxidation behind it. The attack is usually deeper down the grain boundaries. The internal attack of the metal is led by sulfur, which diffuses into the metal faster than oxygen. As oxygen diffuses behind the sulfur, it oxidizes the sulfide particles that have formed because the oxides are more stable than the sulfides. The oxidation of the sulfides releases elemental sulfur, which then diffuses deeper into the metal, producing more sulfides, and the process repeats itself.

Low-temperature hot corrosion, also called type II hot corrosion, occurs at temperatures between 595 and 815 °C (1100 and 1500 °F) with a maximum rate of attack between 675 and 730 °C (1250 and 1350 °F). It is caused by the mixture of alkali sulfates with alloy metal sulfates, such as cobalt sulfate (CoSO_4) or nickel sulfate (NiSO_4), and requires a significant partial pressure of sulfur trioxide (SO_3). This sulfate mixture destroys the oxide scale and its protective ability. The rate of attack can be as great as that for high-temperature hot corrosion.

A micrograph of low-temperature hot corrosion is shown in Fig. 7. Low-temperature hot corrosion results in pitting of the metal surface, a porous layered scale, little base-metal depletion, and few internal sulfides.

Transition Hot Corrosion. Between about 760 and 815 °C (1400 and 1500 °F) there is a form of hot corrosion that has been called transition hot corrosion. This attack is characterized

by the formation of discrete internal sulfides beneath the surface and an oxide scale on the surface. This form of attack is not very aggressive and has not received very much study. It can also occur at temperatures much lower than 760 °C (1400 °F).

Hot Corrosion versus Sulfidation. Hot corrosion is often termed sulfidation because sulfides are formed in the metal or in the scale. However, sulfidation can also refer to the gaseous reaction of sulfur with a metal in a manner similar to oxidation, whereas hot corrosion refers to attack of the metal by molten sulfates.

Elements Influencing Hot Corrosion. Hot corrosion in industrial environments is modified by the presence of other elements, such as calcium, chlorine, unburned carbon, and so forth. Exactly how these other elements affect hot corrosion is not known, but they typically make the hot corrosion more aggressive. As such, one can consider hot corrosion of industrial gas turbines to be caused by a chemical soup, with sulfur and either sodium or potassium as necessary ingredients.

Base Metals and Coatings. Hot corrosion is a serious problem for industrial gas turbines. Base metals have varying degrees of resistance to hot corrosion, ranging from no resistance to good resistance. However, there are no base metals that are so resistant that they can successfully operate continuously in a hot corrosion environment. All base metals will eventually be badly attacked when operated in hot corrosion environments. Base metals for industrial gas turbines are usually selected so that they have some resistance to hot corrosion, although this is not always the case. These alloys have a composition that prevents them from achieving the strength levels of aircraft alloys, which usually have much less resistance to hot corrosion.

Similarly, protective coatings have varying degrees of resistance to hot corrosion, ranging from limited resistance to excellent resistance. However, they also will eventually be compromised and attacked by the hot corrosion environment.

Mitigating Hot Corrosion. The best solution to hot corrosion is to avoid it by removing the contaminants that cause it. Hot corrosion is caused by sulfur plus the presence of alkali

metals, principally sodium and potassium. Usually, the sulfur cannot be economically removed, but sodium and potassium can be. These elements can enter from the air, fuel, or water that is used in the engine. Proper filtration of the air and control of the quality of the fuel and water will eliminate hot corrosion conditions. The amount of allowable sodium and potassium from all sources taken together varies by engine model and typically varies from 0.1 to 2 ppm, with a value of 0.5 ppm being most typical.

Hot Corrosion Caused by Lead and Vanadium. Two other forms of hot corrosion not discussed previously are occasionally seen. These are hot corrosion by lead and hot corrosion by vanadium. Lead hot corrosion is caused by the formation of lead oxide, which melts at 888 °C (1630 °F). Vanadium hot corrosion is caused by vanadium pentoxide, which melts at 690 °C (1275 °F). Neither base metals nor coatings can tolerate these forms of hot corrosion, which are very aggressive. Lead hot corrosion is controlled by ensuring that there is no lead in either the fuel or the air (typically a maximum of 0.1 to 2 ppm is allowed). Vanadium hot corrosion is controlled in the same manner. Vanadium in liquid fuel can be removed by the use of magnesium, which ties up the vanadium.

Effect of High-Temperature Corrosion on Mechanical Properties

The effect of high-temperature oxidation and hot corrosion on the mechanical properties of superalloys is generally negative. Both forms of environmental attack reduce the cross-sectional area of the part, thereby increasing the stresses. More importantly, these forms of attack reduce creep and fatigue life by forming notches in the metal that are either the precursors to fatigue cracks or assist in the growth of existing cracks.

An example of the reduction of creep life is shown in Fig. 8 for several nickel-base superalloys. The rupture life in salt environments that cause hot corrosion can be greatly degraded as compared to the life in air. The effect of the hot corrosion is reduced at low stresses, which indicates that a threshold stress level may exist for each alloy, below which rupture life may become insensitive to hot corrosion.

High-Temperature Coatings

The use of high-temperature coatings is the principal method to provide protection from high-temperature oxidation and hot corrosion in industrial gas turbines. These coatings work by forming a thin oxide barrier on the surface, as shown schematically in Fig. 9. (The oxidation protection of base metals works in the same manner.) This barrier separates the base metal and the coating from the reactive gases and is extremely thin, on the order of 2 μm (100 $\mu\text{in.}$). Without this barrier, the reactive gases would oxidize and corrode the base metal, as well as the coating itself. This oxide barrier is primarily

alumina (Al_2O_3) for high temperatures and chromia (Cr_2O_3) for lower temperatures.

The role of the coating is to form an oxide barrier. Ideally, this barrier is perfectly adherent to the substrate, has no imperfections, and grows very slowly after first forming. Since one cannot achieve ideal oxide barriers, the coating must be able to reform the oxide barrier should some of it become damaged due to cracking, spallation, and so forth. The role of the coating is to act as a reservoir of the oxide-forming elements, which are primarily aluminum and chromium. Thus, these coatings contain as much aluminum and chromium as possible, without making the coating too brittle. As the protective oxide is removed and reformed, the aluminum and chromium content of the coating is reduced. Eventually, the aluminum and chromium levels are too low to reform this protective oxide layer. At this point, the coating itself is attacked by oxidation. As such, the coating is expected to wear out and be replaced by a fresh coating. This is why coatings are called sacrificial.

For hot corrosion conditions, the protective oxide layer is attacked by the molten corrosive on its surface. After an incubation period, the oxide is removed and the coating is then attacked by the molten corrosive. The role of the coating is to form an oxide that maximizes the length of this incubation period.

Types of Protective Coatings. There are two categories of coatings used—diffusion coatings and overlay coatings. Diffusion coatings are formed by diffusing aluminum or chromium into the surface of the material to be coated. Overlay coatings are made by depositing a coating over the surface of the material to be coated.

Fig. 8 Degradation in rupture life for various superalloys due to hot corrosion at 705 °C (1300 °F)

Thermal barrier coatings (TBCs) are a third type of coating that is used in industrial gas turbines. This coating consists of a ceramic layer on top of either a diffusion or overlay coating. The ceramic lowers the temperature of the metal by acting as an insulator, as long as the opposite surface of the part is cooled by some means. If there is no cooling of the opposite surface of the metal, then both the metal and the TBC will eventually reach the same temperature because there is no way to remove the heat that the metal picks up. The diffusion or overlay coating that the ceramic is applied over provides corrosion protection because the ceramic layer is porous to oxygen and molten corrosives. However, the ceramic is not tolerant of molten corrosives. When the engine is cooled down, the molten corrosives inside the ceramic solidify and cause the ceramic to spall off. Because TBCs are designed for thermal protection, as opposed to protection from high-temperature oxidation and hot corrosion, they will not be dealt with further. Their resistance to these forms of environmental attack is the same as the diffusion and overlay coatings discussed below.

The protective elements in coatings, aluminum and chromium, form the protective oxide scale. Nickel and/or cobalt form the matrix of the coatings. Other elements used in coatings, but in smaller quantities, are silicon, platinum, rhodium, palladium, yttrium, hafnium, and tantalum. Silicon improves the hot corrosion resistance. The other elements improve both the oxidation and hot corrosion resistance of the coating.

Yttrium and other rare earth elements improve the adherence of the oxide scale to the substrate by reducing the amount of the oxide that spalls off during a thermal cycle. Platinum, rhodium, and palladium also reduce oxide spalling, due to reasons that are not understood. These elements are sometimes called “active elements” because of their affinity for oxygen. It has been shown that yttrium forms sulfides with sulfur in the coating. If there is free sulfur in the coating, it migrates to the oxide-coating interface, weakening this interface, and increasing the amount of oxide spalling.

Diffusion aluminide coatings are nickel aluminide (NiAl) and cobalt aluminide (CoAl). NiAl forms on nickel-base superalloys and CoAl forms on cobalt-base superalloys. Diffusion chrome coatings are also used. There are various processes used to make these coatings,

Fig. 9 High-temperature coatings protect the base metal by forming a protective oxide, which acts as a barrier to the corrosive gases.

including pack diffusion, chemical vapor deposition, and slurries.

A micrograph of a nickel-aluminide coating is shown in Fig. 10. The coating consists of the protective portion and an interdiffusion zone. The interdiffusion zone contains various intermetallic compounds, including sigma phase, due to the loss of elements from the base metal to form the coating. (This sigma phase is not detrimental.)

Aluminide coatings for industrial gas turbines are usually modified by the addition of chromium (chromium usually comes from the superalloy), silicon, platinum, or other noble metals. Chromium and silicon impart resistance to hot corrosion. Platinum significantly improves the resistance to high-temperature oxidation and high-temperature hot corrosion.

Overlay coatings are a layer of a special alloy selected for resistance to environmental attack and is deposited on the metal surface. Overlay coatings can be made thicker than diffusion coatings, which may provide more protection to the base metal. The microstructure of an overlay coating is shown by the middle portion of the coating in Fig. 11. It consists of intermetallic

Fig. 10 Micrograph of a nickel-aluminide coating. As-polished

Fig. 11 Duplex coating consisting of an overlay coating (O) with an aluminide layer (A) on top. The interdiffusion zone with the base metal (B) is indicated by the letter I. There is another interdiffusion zone between A and O. Lactic acid etch

compounds in a matrix. These compounds are aluminides—NiAl, Ni₃Al, or CoAl. The matrix consists of nickel, cobalt, chromium, and yttrium.

There are a wide variety of overlay coating compositions. These coatings are usually called MCrAlY (pronounced “M crawl-ee”) coatings, since chromium, aluminum, and yttrium are almost always present. The “M” in these coatings is either nickel, cobalt, or a mixture of these elements. The concentrations of the coating elements depend on the intended use of the coating. Other elements such as silicon, hafnium, and tantalum are sometimes added to the coating to improve the performance. Overlay coatings, such as NiCrSi, also can be made without aluminum or yttrium and can provide protection at lower temperatures.

Chromium and aluminum provide the oxidation and hot corrosion resistance of the coating. Their levels are adjusted to provide maximum resistance to one or another form of attack or are balanced to provide protection from several types of attack. Higher aluminum (>8 wt%) is used for oxidation protection, and higher chromium (>23 wt%) is used for protection from low-temperature hot corrosion. In order to be fatigue resistant, the aluminum and chromium levels should be kept low because higher levels reduce the ductility of the coating. However, if these levels are too low, there will be inadequate protection from high-temperature attack.

The majority of the overlay coating is composed of cobalt, nickel, or a combination of the two. Cobalt is better for hot corrosion, and nickel is better for high-temperature oxidation.

A mixture of both cobalt and nickel is a compromise for protection from both types of attack. NiCrAlY coatings are more ductile than CoCrAlY coatings, but NiCoCrAlY coatings can be more ductile than either.

Overlay coatings are generally applied by plasma spray, high-velocity oxyfuel (HVOF) spray, or electron beam physical vapor deposition (EBPVD). Frequently, a diffusion anneal treatment is carried out after coating to obtain diffusion between coating and substrate, which gives good bonding, and homogenizes the as-sprayed microstructure.

Sometimes a diffusion aluminide coating is applied over an overlay coating. These duplex coatings provide increased protection by substantially increasing the aluminum content of the outer layer. However, this increased aluminum level makes these coatings more prone to cracking on the outer layer. The microstructure of a duplex coating is shown in Fig. 11.

The effect of coatings on the mechanical properties of turbine components ranges from beneficial to harmful. If the coating is properly applied, there is usually no effect on the tensile or creep strength of the metal. In high-cycle fatigue, coatings are usually considered to reduce the fatigue life because they crack at higher stresses. In low-cycle fatigue, or thermal mechanical fatigue, coatings will reduce the fatigue life if the stresses or strains are high enough to cause the coating to crack, because the coatings are not as ductile as the metal substrate. However, coatings may prolong the fatigue life if they do not crack, because they prevent the oxidation of the metal substrate, which can be the precursor to the formation of a crack.

Components Susceptible to Dew-Point Corrosion

William Cox, Corrosion Management Ltd.
Wally Huijbregts, Huijbregts Corrosion Consultancy
René Leferink, KEMA

DEW-POINT CORROSION occurs when gas is cooled below the saturation temperature pertinent to the concentration of condensable species contained by a gas. In the context of this article, it is the attack in the low-temperature section of combustion equipment resulting from acidic flue gas vapors that condense and cause corrosion damage to the plant materials. Waste flue gas produced by the combustion of fossil fuels may contain several components, such as sulfur trioxide (SO_3), hydrogen chloride (HCl), nitrogen dioxide (NO_2), carbon dioxide (CO_2), and water (H_2O), and therefore may display several dew-point temperatures at which the various species begin to condense.

Dew Point

The dew point is referred to as the temperature below which a gas must be cooled at constant pressure and constant vapor content in order for saturation to occur. Any additional cooling will result in the formation of a liquid or, at low temperatures, a solid.

In the flue gas of an industrial process, gaseous compounds such as SO_3 , HCl , and NO_2 can be present. These compounds can react easily with water to form solutions of sulfuric acid, hydrochloric acid, and nitric acid, respectively. The dew points of all these solutions are higher than are the dew points of water, which means that these acids will deposit well in advance of water in a flue gas that is being cooled.

Apart from the general corrosion that is caused by the deposition of these acids, other more specific types of corrosion may occur. For example, the presence of hydrochloric acid can produce stress-corrosion cracking (SCC) in austenitic-type stainless steels and nitric acid can cause nitrate SCC in carbon steels.

The dew points of the various gases can be calculated from the formulas of:

- Verhoff (Ref 1) for SO_3 (Fig. 1)
- Kiang (Ref 2) for SO_3 and HCl (Fig. 2)
- Perry (Ref 3) for NO_2 (Fig. 3)

The droplets that condense are often highly concentrated, and acid concentrations in excess of 10% can be expected. At temperatures below the dew point, the acid concentration will decrease according to the boiling line of the acid (for sulfuric acid, see Fig. 4). A gas containing 10 vppm SO_3 and 4% water has a dew point of $\sim 130^\circ\text{C}$ (265°F) as shown in Fig. 1. At this temperature, the first condensed droplets will have a concentration of 85% sulfuric acid (Fig. 4). At a lower temperature of about 40°C (105°F), the concentration will still be approximately 40%.

Components Susceptible to Attack

Corrosion-rate peaks related to individual condensation processes may appear, but the

Fig. 2 Dew-point behavior of HCl at 0.4 and 7% water contents in the gas. Source: Ref 2

formation of protective corrosion products and the deposition of soot ash can moderate the corrosive effects of deposited acids. In conventional boiler plants, the risk areas normally include the posteconomizer flue gas handling sections such as air heaters, ducting and precipitators, induced-draft fans, and chimney stacks.

Dew-point corrosion problems in nominally dry flue gas handling systems are discussed in this section. Dew-point corrosion caused by SO_3 and HCl in fossil-fired power plants and the secondary factors affecting it are thoroughly discussed in Ref 4 and 5. Many of these cases are also valid for waste incinerators. Nitrate SCC in heat-recovery steam generators (HRSGs) is a more recent problem area (Ref 6, 7). Problems in wet flue gas desulfurization (FGD) systems are covered in the article "Corrosion of Flue Gas Desulfurization Systems" in this Volume.

Fig. 3 Dew-point behavior of NO_2 at 0.7 and 4% water content in the gas. Source: Ref 3

Fig. 4 Concentration of condensed sulfuric acid from an SO_3 gas containing 4% water

Most fossil-fired power plants are constructed of carbon steel, and past work largely was conducted on this material. Extensive dew-point corrosion work is reported in Ref 4 and 5. In specialized applications, low-alloy steels, stainless steels, nickel-base alloys, and organic and inorganic coatings are also used. The latest developments are condensing heat-recovery systems. In an effort to extract as much energy as possible from the flue gas, it is cooled to temperatures well below the dew point. This has the benefit that the energy that is released by condensation of water also can be utilized. In addition to water, the acid will be stripped from the flue gas. Due to the excess amount of condensing water, the concentration of the acids will not be so high as is the case where condensation occurs immediately below the dew point. Nevertheless, unprotected carbon steel cannot be used for long periods in condensing heat-recovery systems.

There are several choices for material in a condensing heat-recovery system. These include:

- The regular replacement of carbon steel tubes
- The use of more highly alloyed material
- The application of polymers as listed in Table 1
- The coating of carbon steel tubes with polytetrafluoroethylene (PTFE)

The practice from condensing heat-recovery boilers shows that the equipment and designs are maturing, but problems may still arise. For example, in a PTFE coating, cracks can be formed that result in crevice corrosion of the steel substrate. Additionally, HCl can diffuse through a PTFE coating over time and can result in corrosion of the underlying steel. Net present value calculations can be a powerful method to identify which material is the optimal choice. In 1997 calculations were made by KEMA (the Dutch Electricity Research Institute) for heat-exchanger bundles. The design conditions were: mass flow 700 kg/s (1540 lb/s), temperature 170 °C (340 °F), and pressure 25 bar (300 psig). The materials involved were carbon steel, stainless steel, and polyvinylidene fluoride (PVDF). At that time, regular replacement of the carbon steel tube bundles was found to be the most cost-effective option.

In the early 1990s, several HRSGs of combined cycle power plants in the Netherlands

suffered failures in carbon steel tubes. Cracks were mostly found in the low-temperature heat exchangers, which typically operate at temperatures between 70 and 90 °C (160 and 195 °F), where nitrate condenses from the flue gas.

In some HRSGs, thermal insulation material is mounted on the inside of a closed casing. The advantage is a lower metal temperature of the casing. This will reduce the risk of creep damage to casing steel, and therefore less expensive materials can be used. However, there is a temperature gradient between the inside and outside of the insulation where sulfuric acid, nitric acid, and water can be condensed during startup and shutdown, and even during normal operation conditions. Thus, there is a risk of nitrate SCC not only in the low-temperature heat exchangers, but also in the hot boiler casings.

Dry Flue Gas Handling Systems in Conventional Combustion Systems

A conventional coal-fired power generation boiler is illustrated in Fig. 5; the locations of items prone to dew-point corrosion are indicated. The most susceptible areas are discussed in this section.

Penthouse Casing and Hanger Bars. The penthouse casing encloses the tube header pipework above the boiler furnace roof. Flue gas leakage from the furnace can cause corrosion of the casing and furnace support steelwork. The hanger bars holding the furnace tube bundles are particularly susceptible to attack near the seals retaining the bars passing from the casing to the external environment (Fig. 6). Bars can corrode such that insufficient cross section remains to support the load, and failure allows collapse of the furnace roof and superheater tube bundles.

Air Heater Cold Ends. Air heaters are commonly either of honeycomb matrix (Ljungström or Rothemühle) or shell and tube construction. In both Ljungström and Rothemühle air heaters, energy from the exhaust flue gas is absorbed by metal plates. When the plates then come in

contact with the cold intake air, the heat energy is released. For both heat-exchanger types, damage is usually most severe at the cold end. A Ljungström rotating-matrix air heater is shown schematically in Fig. 7. Rothemühle air heaters are similar except that the matrix is stationary and the flue gas/inlet air is supplied by an arrangement of rotating hoods. In the Ljungström type, the ductwork is stationary, and the heat-exchanger matrix rotates in either a horizontal or a vertical plane.

Corrosion damage is sustained by the thin steel heat-exchanger elements and by support steelwork and air seal materials. It is caused partly by cold air leaking from the inlet to the outlet duct (bypassing the air heater matrix), but damage is often worsened by mechanical interaction between the rotating and fixed components as well as by displaced heat-exchanger elements that have fallen from their baskets. The highest dew-point corrosion rates are often associated with operation of a cold-end soot-blower, which removes fouling deposits by steam or air jets.

Increased dew-point attack seems linked to moisture droplets entrained in the blowing medium impinging directly on the lower edges of the air heater elements, causing dissolution of aggressive salts, removal of protective bonded deposits, mechanical abrasion or erosion of the element surface, and fatigue cracking of the element plates. The local injection of considerable moisture increases the acid dew-point temperature of the flue gas in a region where the metal temperature may already approach this dew point.

In tube-type air heaters, corrosion is again normally found at the cold end. The same temperature and sootblowing parameters described for matrix air heaters also apply to tube-type heaters, but bypass air leakage is not a problem until tubes have been perforated. However, tube air heaters are often prone to poor gas distribution across the heat-exchanger surface. This leads to localized cool spots where dew-point corrosion takes place (Ref 6).

Table 1 Polymers used in condensing heat-recovery systems

Type	Maximum temperature		Cost ratio
	°C	°F	
Polypropylene (PP)	80(a)	175(a)	1
Polyvinylidene fluoride (PVDF)	150(b)	300(b)	25
Perfluoralkoxy copolymer (PFA)	240	465	55
Polyetherketone based (PEEK)	300–330	570–625	95

(a) At 2 to 3 atm. (b) At 5 to 6 atm

Fig. 5 Fossil-fired power generation boiler showing areas susceptible to dew-point corrosion (black areas)

Ductwork, Expansion Joints, Inspection or Sampling Ports, and Access Doors. Damage at the locations shown in Fig. 5 is often caused by constant low operating temperatures, which normally are related to air entry at fabrication faults, leaking expansion joints and door seals, or careless replacement of sampling port covers. Such leaks can cause an appreciable reduction in duct metal temperature due to stratification effects within the gas stream. Attack rates of 5 mm/yr (200 mils/yr) have been reported in precipitator outlet manifold ductwork. Such

damage substantially affects ductwork integrity and frequently leads to increased attack rates on plant components downstream, particularly on the electrostatic precipitator housing and fittings and on the chimney stack.

Electrostatic Precipitators and Filter Bag Houses. Fly ash precipitators are not normally used on oil- or gas-fired equipment, but are usually present on coal-fired systems or incinerator exhaust streams. Filter bags are sometimes used instead; however, both methods of dust collection are located in large insulated housings, and their internal components are expensive to maintain and replace.

Precipitator housings are normally constructed of low-carbon steel and concrete. Corrosion attack of the housing is often associated with high levels of air in-leakage upstream due to inadequate maintenance or poor housekeeping. Occasionally, poor internal gas flow distribution may allow cool zones to develop, especially under low-flow conditions. Damage appears as casing perforation and sulfation or spalling of concrete, corrosion of rebar, and loss of structural integrity.

Damage to precipitator components is very expensive and necessitates plant shutdown for repair or replacement. Low-carbon steel collector plates and emitter wires may sustain attack during in-service periods of low flue gas temperature, which result from excessive air entry upstream of the precipitators or from inadequate sealing of the dust discharge doors and plate suspension masts (Fig. 8). Off-line attack resulting from the sweating of acid-saturated pulverized fuel ash may also be important. Precipitator plate attack is more marked because the thin-gage plates are attacked simultaneously from both sides, effectively doubling the plate thinning rate.

Filter bag installations normally are less expensive than are precipitators, but require

more maintenance. Dew-point corrosion frequently is displayed on the housings because repeated access to replace holed or detached bags tends to cause wear to access door seals. Low-temperature operation or frequent startup routines may subject the bag house, bag supports, and rapping equipment to extended periods of corrosion attack; this causes blinding of bags and premature holing of the bag material due to chafing during operation or rapping cycles (Ref 8).

Induced-Draft Fan Seals. Corrosion damage to the induced-draft fan housings, control vanes, and impeller seals again is due to air in-leakage. Severe damage normally is associated with the neglect of seal condition, and attack of the fan housing itself rapidly can become severe if neglected. Fan housing washing drains should not be left open when the fan is in service. Impeller damage is less common because this component contacts the bulk flue gas.

Chimney Stacks. The stack is often the most vulnerable unit in the gas-handling system because it experiences the results of poorly controlled operation of the furnace and other components of the gas train. Damage normally is due to continuous condensation during operation and the buildup of agglomerated deposits that insulate the stack inner surface. Stack temperature monitoring often is ignored or neglected. Stacks frequently suffer severe attack before the damage is evident, and inconvenient emergency repairs, necessitating unscheduled unit shutdown, must be made. Damage can occur to liners and/or to the body of the structure, whether it is low-carbon steel, nickel alloy, or concrete (Fig. 9). In prefabricated sectional steel stacks, corrosion occurs preferentially on the inner surface near the external flanges or ladder attachments because of local cooling effects.

Heat-Recovery Steam Generators in Gas Turbines

In recent years gas turbines fueled on natural gas have become increasingly popular. To in-

Fig. 6 Hangar bar packing box showing areas prone to corrosion. Source: Ref 4

Fig. 7 Ljungström air heater showing the locations of the air seal and cold end basket corrosion sites

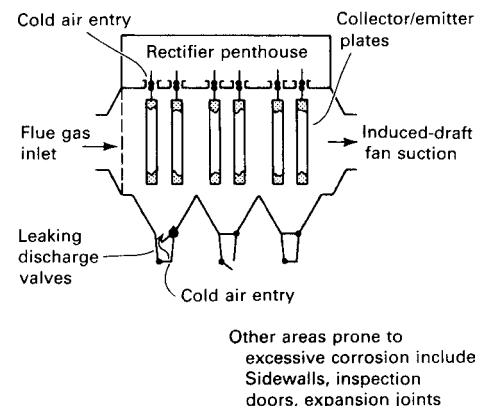

Fig. 8 Electrostatic precipitator showing areas prone to excessive corrosion

crease the total efficiency and the versatility of gas turbine powered installations, the hot exhaust gases from the combustion turbine, at temperatures in excess of 500 °C (930 °F), are cooled in a HRSG. Experience of nitrate SCC in HRSGs has been described in detail in Ref 6 and 7.

Low-Temperature Heat Exchangers. In general, the heat exchangers are fabricated from a standard low-carbon steel used for construction purposes. In some cases soon after going into service (i.e., within one year) nitrate-induced SCC can occur in the HRSGs. Most observed cracking occurs in bends and finned tubes where mechanical stresses were relatively high. Microscopic analyses of samples revealed that intergranular corrosion had occurred, and it was frequently reported that complete grains of material had become detached. A cross section of a cracked tube is depicted in Fig. 10.

It was discovered that in deposits found near cracked pipes on failed heat exchangers, both sulfates and nitrates were present. The large amount of sulfate in the deposits was explained by the presence of sulfur salts in the intake air. If air filters are used, these salts can be removed from the air. However, during conditions of atmospheric fog, small moisture droplets precipitate onto the filters. Salts in the air filter dissolve in these droplets. If the fog conditions persist for a longer period, the air filter will become saturated with water and salt-containing droplets can be sucked into the combustion air, thereby entering the gas turbine.

Ammonium nitrate deposits have been found in the cooler parts of such waste-heat-recovery boilers, close to the stack. Under normal conditions, the flue gas will be cooled to about 80 °C (175 °F). However, below 170 °C (340 °F), ammonium nitrate is solid and is most likely to be deposited on the tube walls. Because ammonium nitrate will not leave the boiler in a vapor state, it accumulates over time on the heat-exchanger surfaces near to the stack. Ammonium nitrate is hygroscopic and is easily dissolved in water. During startup and shutdown periods, when the local temperature is below the water dew point a liquid film containing up to 75%

ammonium nitrate can be expected on the wall. At 60 °C (140 °F), the ammonium nitrate concentration of the liquid can increase to as much as 80% (10 mol/L). In these environments intergranular corrosion of carbon steel and low-alloy steel will occur easily, initiating the stress-assisted intergranular corrosion or SCC.

Cold Casings. In some HRSGs, thermal insulation material is mounted on the inside of the casing. Thus, there is a temperature gradient between the inside and outside of the insulation, where sulfuric acid, nitric acid, and water can be condensed during startup and shutdown periods, and even during normal operation. Sulfuric and nitric acid will react with the insulation forming calcium nitrates. Calcium and ammonium nitrates are both environments where intergranular SCC in carbon steel will be initiated very easily. Calcium and ammonium nitrate both are hygroscopic materials that can take up water even above the dew point of a gas. Up to a temperature of 120 °C (250 °F), this can create a very corrosive environment and may result in a severe risk of nitrate SCC in susceptible materials.

Mitigation of Dew-Point Corrosion

In boiler technology, the "acid dew point" usually means the sulfuric acid dew-point temperature, because this is the highest temperature at which acid condensation occurs. Earlier studies showed that, in dust-free flue gases, low-carbon steel corrosion reaches a maximum at about 25 to 50 °C (45 to 90 °F) below the acid dew-point temperature. More recently (Ref 4), it has been seen that at much lower temperatures (below 60 °C, or 140 °F) the corrosion rate of low-carbon steel increases rapidly to at least twice the high-temperature maximum, and to at

least three times the high-temperature maximum if HCl is present (Fig. 11).

During the period from 1942 to 1955, it was found difficult to define a precise temperature below which rapid corrosion would start and continue; therefore, a threshold value was sought above which the plant could be operated confidently. A dew-point probe and meter was developed to identify the dew-point temperature, and maintenance of the flue gas temperature at 20 to 30 °C (36 to 54 °F) higher than the dew-point temperature was recommended to avoid condensation and corrosion.

Increasing fuel costs, higher overall efficiencies, and environmental considerations have focused renewed effort on this subject and the re-examination of earlier philosophies. The drive toward less expensive low-grade (more sulfur-rich) fuels, together with improved heat extraction processes, has produced a move toward lower back-end temperatures with better combustion control, materials selection, and use of additives to minimize dew-point corrosion. A further refinement arises from the development of continuous in-plant monitors of dew-point corrosion that can identify harmful operating regions directly.

It is difficult to give blanket advice on lessening dew-point corrosion problems because much depends on the precise plant configuration and service environment. However, general comments on materials selection, plant operation, use of neutralizing additives, maintenance, good housekeeping, and lagging (insulation) are offered in the sections that follow.

Materials Selection

Sulfuric Acid Dew Point. Most power boiler exhaust components are made of carbon steel. The material can last indefinitely in conventional plants if metal temperature is maintained above the acid dew-point temperature when the plant is in service and if reasonable care is taken to prevent excessive off-line attack during shutdown periods. In marginal conditions, cast iron may extend service life, but normally this is simply due to its greater cross section.

A few low-alloy steels have shown superior performance to low-carbon steel in particular applications. Notably, Cor-Ten, a high-strength low-alloy weathering steel, has been used with fair success for cold-end air heater elements. The improved corrosion performance seems related to the formation of a thin protective layer of corrosion product. Care must be taken to ensure that a cyclic wet/dry operating regime occurs, especially during the early period of exposure. Continuous exposure in the wet condition can result in higher corrosion rates than may occur on plain carbon steel.

Expensive alloy materials have been used where plain-carbon steel corrosion is severe, but they have not always been successful. The good but sometimes unreliable performance of such materials is due to the presence of a preformed

Fig. 9 Chimney stack showing sites prone to corrosion

Fig. 10 Intergranular nitrate SCC in a low-temperature heat exchanger

protective oxide. Failure is associated with deposit formation, which causes differential aeration and concentration cells, producing pitting attack.

Coating use is hazardous because of difficulties in surface preparation, quality of application, physical durability, adhesion under cycling temperature, and dust abrasion. However, in certain practical application tests, good performance has been reported. For concrete stack lining in power stations, an expensive fluoroelastomer has given outstanding protection against acid dew-point attack, but the material is permeable to moisture and hence is unsuitable for use on a carbon steel substrate. Less expensive modified coal tar epoxy has performed well in some applications, but good quality surface preparation is critical. Glass flake polyester coatings can be satisfactory provided that the substrate cannot flex, especially during cold weather, because such coatings can be very brittle at low temperatures. An isocyanate-cured epoxy material has also been successful in less troublesome plant conditions. For air heater elements, double-dipped enamel coatings are likely to be most effective, though such coatings add significantly to the capital cost. Major difficulties in ensuring defect-free adherent coatings have occurred with arc sprayed aluminum, chromia, and alumina materials, but arc sprayed aluminum has been reported to be generally satisfactory for high-temperature gas turbine stack applications. However, in these stacks, severe thermal conditions can lead to exfoliation and acidic rust flaking.

Nitric Acid Dew Point. The use of stressed carbon steels in conditions where there is a risk

of condensation in the presence of nitrates or NO_x means that there is a substantial probability that SCC is likely to occur, sooner or later. Stress-corrosion cracking due to nitrates is nearly always associated with intergranular corrosion. Leferink (Ref 7) studied the resistance of several ferritic steels to intergranular corrosion in ammonium nitrate solutions in the range of 2 to 35 wt% at 90 °C (195 °F) for a period of 100 h. A clear correlation was observed between the steel composition and the concentrations of ammonium nitrate that were necessary to support intergranular corrosion. For all of the tested steels: carbon steel, 15Mo3 steel, 1Cr-0.4Mo steel, 2.25Cr-1Mo steel, and 12% Cr steel, the correlation was:

$$\text{Critical percentage ammonium nitrate (wt\%)} \\ = 6\text{Mo} + 2\text{Cr} + 1\text{Mn} + 8 - 12\text{Si} - 8\text{Cu} - 1\text{C}$$

As nitrate-induced intergranular corrosion is often a precursor to intergranular SCC, SCC is particularly influenced by chemical corrosion. Annealing a material, or the selection of a higher-strength material, will be of minimal help in preventing SCC on the longer term. The selection of a low-alloyed 2.25Cr-1Mo steel as a replacement for carbon steel in critical locations, in general, is a better choice for the prevention of intergranular corrosion in dissolved nitrate environments.

Plant Operation

Sulfuric Acid Dew Point. Although materials selection can be pertinent in certain plant components, careful plant operation, good

housekeeping, and comprehensive maintenance represent a major and more general route to technically efficient, fuel economical, and cost-effective operation. Classical dew-point conditions do not necessarily yield unacceptably high corrosion rates in practice. Control of the secondary factors alone can lead to significant savings by minimizing replacement costs in key areas. Improved on-line monitoring capabilities allow the onset of corrosion to be detected and avoided, often by minor operational refinement, and the possibility of lowering back-end temperatures without risk to the plant can be explored confidently. Precise operational control is important. The inherent variability of excess oxygen, furnace temperature, combustion method, and fuel ashing characteristics can affect low-temperature corrosion more than changes in fuel sulfur content.

Nitric Acid Dew Point. Even though knowledge of the condensation of corrosive gases is available in the literature, condensation of acids other than sulfuric acid frequently is overlooked at the design stage. This leads to many failures in technical installations. The operation of equipment that can generate condensing gases makes it necessary to think carefully about the operational regimes (both on- and off-line) and of the possible risk of acid condensation attack. The condensation of nitric acid can cause SCC of carbon steel. However, reaction products of nitric acid with the steel or insulation also can result in the formation of corrosive ammonium nitrate or calcium nitrate. As mentioned previously, calcium and ammonium nitrate both are hygroscopic materials that can take up water even above the dew point of a gas and up to a temperature of 120 °C (250 °F). This can create a corrosive environment that may result in nitrate SCC in susceptible materials. Cold boiler/combustion plant casings can be used only at very low NO_2 levels. Even at NO_2 levels below 20 vppm, there is a danger that nitrates will accumulate in the insulation after prolonged periods of operation.

Maintenance, Good Housekeeping, and Lagging

A good housekeeping list can be established by adequate planned maintenance procedures introduced for any particular installation because practical dew-point factors are now better understood. Poorly designed or maintained thermal insulation, badly sealed inspection doors, leaking expansion joints, and so on, are unacceptable if future installations are to operate at optimum levels.

Additives

Sulfuric Acid Dew Point. Neutralizing additives, usually calcium or magnesium oxide/hydroxide, tend to have an ad hoc usage, especially in oil-fired situations. Their benefit in preventing acid smuts is proven, but their ability

Fig. 11 Modified acid dew-point curve showing the corrosion rate of freshly prepared plain-carbon steel surface exposed to dust-free flue gas in a laboratory test rig. The increase in corrosion rate at lower temperatures in the presence of HCl is shown. The modification of classic dew-point corrosion behavior in coal-fired power plants also is indicated.

to reduce corrosion rates consistently is less certain. Modern electrochemical monitoring techniques can provide a continuous means of assessing additive performance, although in many cases fluctuations in fuel composition and operational control may mask the contribution of the additive. Direct injection of ammonia has been employed to reduce flue gas acidity, but the resultant formation of sticky bisulfite deposits can lead to severe fouling.

Nitric Acid Dew Point. No additives are available to prevent nitrate SCC.

Guidance for Specific Sections of the Plant

Penthouse Casing and Hanger Bars. The casing and hanger bars should be maintained during operation at a temperature in excess of the acid dew-point temperature. This is achieved by external insulation of all items. Hanger bar packing boxes should be routinely checked to ensure that excessive clearance has not developed between the packing and the bar, allowing flue gas leakage. This is especially important above the superheater pendant tubes, which tend to require more maintenance than do other tube bundles (Ref 4).

Air Heater Cold Ends. In matrix-type air heaters, air leakage should be controlled, possibly by allowing only a predetermined acceptable leakage rate, and condensate injection should be prevented, especially that due to leaking soot-blower steam isolation valves. Compressed air is preferred as the blower medium, and slight preheating to dry the air should be considered. Adequate condensate drainage facilities must be maintained for all types of blowers. Air heaters should not be water washed on-line unless absolutely necessary, but thorough water washing off-line is recommended. In many cases, the need to do this may point to inadequate operational control, for example, during low-road conditions. For lower outlet flue gas temperature units, the use of Cor-Ten steel or double-dipped enameled elements should be considered for severe service. Adequate specification and coating quality control must be ensured when using enameled elements. Good gas distribution

across the air heater minimizes cold spots. The use of fuel additives should be considered for combating unavoidable corrosion attack.

Special care should be taken in shell and tube air heaters to ensure good temperature distribution across the unit. Buildup of gas-side deposits, which may allow sub-dew-point metal temperatures to occur beneath, must not be permitted. Deposits (iron sulfates, ash, fly-ash) are rather hygroscopic and corrosive during shutdown situations. Sulfur dioxide will be absorbed and oxidized to SO_3 in presence of ash and increase the corrosiveness. Leakage from perforated cold-end tubes must be minimized (Ref 5).

Ductwork, Expansion Joints, Sampling Ports, and Access Doors. All air in-leakage must be prevented. Door seals should be replaced routinely, and a gas-tight fit ensured. Thermal insulation should be maintained in good condition, leaking expansion joints replaced, and sampling port covers properly refitted after use.

Electrostatic Precipitators and Filter Bag Houses. Adequate maintenance can prevent cold air entry, especially at discharge doors and electrode support masts and at access door seals. External lagging must be in good condition to maintain housing temperature above the acid dew point. Air entry upstream of the precipitator or bag house should be minimized. If possible, the unit should be kept warm during hot-standby conditions. Operation periods in low gas flow or startup conditions should be minimized.

Induced-Draft Fan Seals. These seals should be maintained in good condition on a routine basis. Fan housing washing drains should not be left uncovered.

Stacks. Adequate temperature monitoring should be ensured at top and bottom. Stack operating temperature should be maintained within design limits at all times. For low-carbon steel stacks, adequate insulation and lining conditions must be ensured. Stacks should not be run wet or cold unless specifically designed to do so. Routine inspection programs, for monitoring stack lining and structural integrity, should be initiated.

Low-Temperature Heat Exchangers in HRSG of Gas Turbines. The gas cannot be cooled too much because of the danger of nitric

acid and ammonium nitrate formation. Regular inspection of the tube surfaces is necessary. A continuous monitoring system is advised.

Cold Casing in HRSG of Gas Turbines. Cold HRSG casings are especially vulnerable to dew-point attack because the condensation occurs in the insulation and near the carbon steel casing. A hot (closed) casing with insulation on the exterior is considered the preferred choice.

Corrosion of Generators

William G. Moore, National Electric Coil

A SIGNIFICANT DISCOVERY in the corrosion of generators occurred in the 1990s—crevice-corrosion cracking in water-cooled generators. Before delving into crevice-corrosion cracking, however, this article reviews the generator industry experience with stress-corrosion cracking (SCC) of 18Mn-5Cr alloy retaining rings. This alloy was primarily 18% Mn and 5% Cr. Chemical composition details of this nonmagnetic alloy, used for generator retaining rings, can be found in ASTM A 289 (Class B).

Retaining-Ring Corrosion

Retaining rings support the generator rotor end turn coils during rotation and are under residual stresses and severe operating stresses. In the presence of moisture or other corrodents, and this high operating stress, this 18Mn-5Cr material has been shown to be highly susceptible to SCC. Figure 1 shows fluorescent dye penetrant indications of SCC on the inner retaining ring surface. This ring had been part of a rotor stored in uncontrolled conditions for about 5 years.

Failures in the industry prior to 1987 had been documented in published papers (Ref 1, 2). Of course, failure of a retaining ring inside an operating generator can cause extensive damage and is a threat to the safety of those nearby. As a minimum, failure of a ring requires replacement of the stator winding, stator core, and the rotor winding, and could possibly extend to damage to the generator frame and rotor forging. The loss of generating capacity is a significant cost.

Fortunately, from 1987 to the present, original equipment manufacturers and independent repair shops have pursued an aggressive approach of nondestructive examination of the 18Mn-5Cr rings and replacement with a superior alloy resistant to SCC. This superior alloy is made from 18% Mn and 18% Cr (18Mn-18Cr). This material substitution has kept catastrophic failures to a minimum, but has cost the industry millions of dollars. One industry failure of the 18Mn-18Cr material has been documented, but the root cause is suspected to be primarily due to heavy concentration of chlorides, rather than moisture alone causing SCC. The 18Mn-18Cr

composition is now the only composition that satisfies ASTM A 289/289M.

Many 18Mn-5Cr rings are still in operation on generator rotors today. It is important to minimize moisture in the generator at all times and to inspect the rings if exposed to moisture. In operation, moisture can be minimized by maintaining a high level of hydrogen purity through a hydrogen gas dryer and filter. There is a higher probability of SCC damage occurring to 18Mn-5Cr rings during the shutdown process. If the coolant gas dew point is higher than the retaining-ring temperature, moisture will condense on the rings, which can lead to SCC (Ref 3). Hydrogen coolers should be inspected at major outages for leaks, and tubes must be plugged as necessary.

A higher probability of SCC can occur if the rotor is pulled out of the stator and left sitting on the turbine deck or shop floor. The rings are still under high stress at this time due to the designed prestressing of large shrink fits. Condensation and resulting moisture on the rings should be prevented by turning on the strip heaters in air-cooled machines, or if the rotor is out of the stator, enclosing it in a tarp with some heaters or lamps underneath sufficient to maintain the rotor above the dew point.

Corrosion of magnetic retaining rings is also a concern (Ref 4). Magnetic retaining rings were mostly used on older generators manufactured prior to about 1965. These units tend

to be smaller, but in the presence of moisture can rust and pit as shown in Fig. 2.

As with nonmagnetic rings, pits due to corrosion in magnetic rings can initiate cracking. Especially susceptible are rings that operate in hydrogen, are made of very hard materials (>38 HRC), and were manufactured prior to about 1960. Magnetic rings are more easily repairable than nonmagnetic.

Crevice-Corrosion Cracking in Water-Cooled Generators

Another serious corrosion issue that is unique to water-cooled generators has developed on a specific class and age of units. The problem was first recognized and publicized in the very early 1990s and has become a major concern due to the costs related to solving the problem. The problem occurs only on generators with stator windings that are water cooled. Units

Fig. 1 Fluorescent dye penetrant examination showing linear indications of stress-corrosion cracking in an 18Mn-5Cr retaining ring

Fig. 2 Corrosion-related pitting on surface of magnetic retaining ring

manufactured from about 1970 to 1986, estimated to be about 350 in total, can develop water leaks (Ref 5). These leaks allow cooling water to penetrate the coil insulation, reducing the dielectric strength of the insulation, eventually causing a phase-to-ground electrical fault in the generator. This will trip the unit off-line. Consequential damage to the stator winding and stator core can also occur, often requiring a stator rewind and core repair.

The problem occurs specifically at a brazed connection at the end of the stator coil. The braze material, which joins the copper clip or sleeve to the hollow strand bundle, is relatively porous in nature. Stator coil cooling water can become trapped in these porous openings. The water corrodes the phosphorus rich braze material, eventually finding its way through the hollow copper strand, creating a leak path.

Figures 3 and 4 show the location of this crevice-corrosion cracking in generator water-cooled stator coils.

Research is ongoing about the corrosion mechanism, levels of dissolved oxygen, and various alternative repair mechanisms. There are three primary repair alternatives to address

Fig. 3 End of a water-cooled coil. This "bottle clip," made of copper, allows the coil to be electrically connected to the next coil by means of the laminated flexible connector and also provides a means of cooling water to pass through this coil and out the machine.

corrosion in water cooled coils. The first repair option, pioneered by the OEM, is to inject epoxy resin into the "strand package" area. The intent is to allow the epoxy resin to fill existing crevices and pockets in the porous braze material, preventing water from entering these areas in the future and causing a reinitiation of the corrosion process.

The second repair option is to completely remove the clip assembly at the end of the stator coil, replacing it with a new clip-to-strand connection. A patented, two-piece clip design (Ref 6) allows two separate brazes to be made at two different temperatures. This option allows better access to the strand package during brazing and ultimately allows better control of the brazing process. This process, in conjunction with improved braze material, eliminates the porosity in the braze material, eliminating pockets where cooling water can collect and stagnate. This prevents initiation of crevice-corrosion cracking.

Fig. 4 Boreoscopic view through the bottle clip opening into the strand package, which consists of hollow strands that carry cooling water and solid strands that carry the majority of the current. This bundle of copper strands (both the hollow and solid) are brazed together into a single, consolidated "strand package." Braze material, which is porous, covers the surface of the strands, and extends axially back into the coil between strands. It is this material that is susceptible to crevice-corrosion cracking as cooling water is trapped in the porous openings and initiates the corrosion process.

The third alternative is to rewind the stator with completely new coils, utilizing an improved clip-to-strand design, new materials and braze alloys, and better controlled processes as described previously. The coil rewind option is often necessary if the crevice-corrosion cracking on the existing coils has progressed substantially to the point that a single coil, or more than one coil, has developed leaks, ultimately damaging the coil insulation.

All three alternatives, along with improved efforts to monitor and control oxygen content in the cooling water, have been in practice for a few years and proven to be successful in addressing the issue of corrosion in water-cooled generators.

Corrosion and Erosion of Ash-Handling Systems

ASH HANDLING is a major challenge for utilities and industries using coal as a primary fuel. The combustion process—cyclone, pulverized-coal, or fluidized-bed firing—determines the type and characteristics of the ash. Waste ash, fly ash, and bottom ash are generated in large volumes and must be dealt with in an environmentally acceptable manner. Fly ash comprises small dustlike particles (100 μm or less in diameter); bottom ash consists of much larger slag particles removed at furnace bottoms.

Conventional ash-handling systems collect, convey, and dispose of waste ash by methods that depend on site-specific considerations, government regulations, and economic considerations. Generally, the ash will be handled wet or dry, but the handling system may include combinations of wet and dry conveying. Fly ash is collected dry and is typically conveyed dry for storage or disposal. Wet conveying and storage of fly ash has become environmentally more difficult, and regulations now favor dry conveying systems. Bottom ash is collected in a water bath and is almost always handled wet. Most ash-handling systems convey bottom ash and fly ash separately to storage or disposal, but conveyance in the same pipeline is also acceptable.

Typical operating problems associated with conventional fly ash/bottom ash handling systems may be grouped into two categories:

- Corrosion and erosion (material deterioration)
- Scaling and plugging (material buildup)

These problem areas must be addressed by designers of ash-handling systems and plant operators, who should consider factors such as equipment selection, materials applications, maintenance policy, and system concept. The handling system concepts for fly ash/bottom ash are dry/dry, dry/wet, wet/dry, or wet/wet. The subject of ash handling is discussed in detail in Ref 1.

Fly Ash Systems

Corrosion and corrosion-related problems are more prevalent in wet systems than they are in

dry systems. Both systems are reviewed subsequently.

Dry Fly Ash Systems. The pneumatic conveying of coal ash particles can produce plugging of conveying lines, sticking of the ash to chutes and hoppers, and erosion of internal parts of ash-handling equipment. Corrosion of internal components is normally small to nonexistent. Only the introduction of unwanted moisture would create an environment that produces corrosion severe enough to cause system outages or to require frequent maintenance.

Wet Fly Ash Systems. The transport of fly ash with water as the conveying medium is normally achieved by using a slurry of 10 to 15% ash by weight. The introduction of conveying water sets up an array of water chemistry situations that can lead to scaling and/or corrosion. The tendency for scaling and corrosion depends in part on the chemical characteristics of the ash sludge water and in part on the composition of coal ash.

Table 1 shows the variations in coal ash composition with coal type. The soluble ash species of elements such as iron, calcium, sodium, magnesium, potassium, and a variety of trace elements produce a wide range of pH levels in the ash slurry. For example, a dramatic change in coal supply can result in changes of 1 to 2 pH units. The dominant alkaline constituents are Fe_2O_3 , CaO , MgO , Na_2O , and K_2O ; the acid constituents are SiO_2 , Al_2O_3 , and TiO_2 (Ref 2). This interaction of water and ash is the cause of most corrosion problems.

Scale formation on equipment internals and pipeline walls is always a frequent maintenance problem. The composition of typical scale indicates that compounds of calcium, magnesium, sodium, and silica are available to go into

solution, concentrate, and precipitate out on internal surfaces. The reduction in pipeline diameter caused by heavy scale buildup, the reduction in pump and valve internal clearance by scaling, and the plugging of small control lines often requires dismantling and descaling, or eventual replacement. Most corrosion and erosion-related failures are complicated by scale formation.

Wet Bottom Ash Systems

Hot ash (clinkers or agglomerated slag) deposits of varying sizes are quenched and collected for conveying in the bottom ash system. Bottom ash systems are generally conveyed wet from collection to final disposal. However, some systems incorporate dewatering equipment and haul the ash by mobile equipment or belt conveyors to suitable disposal sites. The pumping and pipeline conveying of bottom ash slurries (normally 15 to 20% ash by weight) generally results in a highly abrasive but only moderately corrosive condition. Agglomerated granular (fused) bottom ash, with its irregular shape and large size, gives the slurry its abrasive nature. Compared with fly ash, bottom ash is inert and insoluble; therefore, chemical interaction between the bottom ash and conveying water is less worrisome.

Current environmental regulations have resulted in the development of the zero-discharge (closed-loop) system. The reuse of conveying water in either bottom ash or fly ash systems concentrates soluble salts and will usually result in more corrosive water chemistry. While most failures result from erosion, scaling,

Table 1 Variations in coal ash composition by coal type

Coal type	Composition, %									
	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	Na_2O	K_2O	SO_3	Ash
Anthracite	48–68	25–44	2–10	1–2	0.2–4	0.2–1	0.1–1	4–19
Bituminous	7–68	4–39	2–44	0.5–4	0.7–36	0.1–4	0.2–3	0.2–4	0.1–32	3–32
Subbituminous	17–58	4–35	3–19	0.6–2	2.2–52	0.5–8	3–16	3–16
Lignite	6–40	4–26	1–34	0–8	12.4–52	2.8–14	0.2–28	0.1–1.3	8.3–32	4–19

Source: Ref 1

or plugging, corrosion may become a problem if soluble salts are allowed to accumulate too long in closed-loop systems.

Mitigating the Problems

Operating problems due to corrosion, erosion, scaling, and plugging can be minimized by consideration of the following:

- Piping systems should have gradual bends, turns, and transitions and should be without sharp angles to reduce erosion and/or plugging.
- Materials of construction (metals, nonmetals, and coatings) that are resistant to acid attack should be selected.
- All storage vessels should have constant agitation to keep solids in suspension to facilitate pumping.
- Pipe diameters and line velocity must be such that suspended solids do not cause plugging.
- Piping systems should be flushed during shutdown to remove solids before solids cementation reactions can occur.
- Abrasive-resistant liners (replaceable metal, plastic, ceramic, and elastomers) or surface treatments should be selected for system components (pump impellers and casings, agitator blades, and pipe liners) for better control of erosion and corrosion of wetted parts.

It is not possible to recommend a single approach or a material of construction that will work for every ash-handling application. Corrosion problems are reduced and equipment lifetime is extended by good case-by-case materials selection, the existence of adequate quality control, operational simplicity, and the use of effective inspection/maintenance practices.

The Future

Present and pending regulations (mainly federal in the United States) tend to restrict the wet-dry options for utility and industry owners. Future systems for fly ash will be dry processes and will require suitable reuse or environmentally safe disposal of the ash. Wet systems for both bottom ash and combined fly ash/bottom ash will drift to the zero-discharge concept and recycle their conveying water.

The article "Environmental Performance of Concrete" in *ASM Handbook*, Vol 13B discusses the advantages of using fly ash as a cementitious material. In the United States in 2000, approximately one-third of the more than 100 million tons of coal combustion products were recycled (Ref 3). In order to meet specifications for use in concrete, the fly ash requires further processing. This equipment is subject to the corrosion and erosion of fly ash in a more aggressive environment.

Corrosion in Portable Energy Sources

Chester M. Dacres, DACCO SCI, Inc.

BATTERIES AND FUEL CELLS are popular forms of portable electrical energy sources. A battery is a device that uses electrochemical processes to convert chemical energy into electrical energy. Batteries are classified into two groups: primary or nonrechargeable batteries, which are discarded after a single use, and secondary or rechargeable batteries, which can be recharged by reversing the flow of current through the electrodes to reconstitute the chemical reactants to their original state (Ref 1).

Batteries and fuel cells make constructive use of electrochemical reactions by converting chemical energy to electrical energy. The design and materials used to construct these devices must address the destructive aspect of reactions present in order to assure useful service life for the devices. This article provides a look at the operation and corrosion problems inherent in batteries and fuel cells. The articles "Anodes for Batteries" and "Fuel Cells" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003, address the constructive aspects of corrosion mechanisms. The article "Corrosion in Fuel Cells" in this Volume provides details of research and development of fuel cells.

Fuel cells are devices similar in purpose and construction to storage batteries; however, they continuously convert energy from various chemicals (fuels) directly into energy. In a fuel cell, the electrochemical reaction of a fuel and an oxidant directly generates a flow of electric current when power is demanded of the cell by an external load. There is no intermediary stage where energy must be expended to produce heat before producing power, and there are no moving parts. Fuel cells are highly efficient, noiseless, and generate relatively less heat and toxic fumes than do internal combustion engines. Fuel cells can be thought of as batteries that do not wear out, do not need recharging, and are lighter in weight (Ref 2).

Battery Types

A battery consists of a negative electrode (anode) from which electrons flow into the external circuit. The reactions at the negative electrodes usually involve strong reductants,

which tend to give up electrons while forming positive ions or cations. A battery also has a positive electrode (cathode) into which electrons flow from the external circuit. The reactants at the positive electrode are usually strong oxidizing agents that accept electrons with ease, while forming negative ions or anions. The third component of a battery is the electrolyte that allows ionic conduction between the positive electrode and the negative electrode. The electrolyte in this type of galvanic cell need not be limited to a liquid solution but may in some cases be a solid ionic conductor. A battery can also have a separator, which is an inert porous insulating medium or an ion-selective permeable membrane that permits the movement of ions between the electrodes while physically separating the electrodes. There are a number of galvanic cells that could be classified as batteries; however, the ones listed in Table 1 are commercially available nonrechargeable and rechargeable batteries (Ref 1).

Corrosion of Batteries

The tendency of metals to oxidize during battery discharge is reflected in their negative Gibbs free energy change. Metals that oxidize more readily have more negative Gibbs free energy change and are considered better anodes for batteries. Battery performance depends not

only on this free energy change but on how much of this energy can be extracted from a given mass of metal during the corrosion reaction when the battery discharges. Some batteries are comprised of many components that are susceptible to corrosion. For example, lithium-sulfur dioxide (LiSO_2) batteries have several parts that corrode and can contribute to a short battery life. The electrolyte in the LiSO_2 batteries contains LiBr as the electrolyte salt and SO_2 as the cathode reactant. The electrolyte dissolves in acetonitrile and sometimes mixes with propylene carbonate. Hardware corrosion problems in LiSO_2 cells include glass corrosion, tantalum corrosion in welded regions, corrosion of lithium in contact with nickel, and stress-corrosion cracking of the battery case. Figure 1 shows each of these sites on a simplified battery schematic (Ref 3–5). Glass corrosion is primarily the result of attack by lithium metal to produce lithium oxide:

The corrosion product Li_2O further corrodes the glass:

The mechanism of glass corrosion is common to all lithium cells in which a liquid electrolyte containing lithium ions (Li^+) wets the glass, and

Table 1 Commercial primary and secondary batteries

Battery system	Net electrochemical reaction
Secondary (rechargeable)	
Lead-acid	$\text{PbO}_2 + \text{Pb} + 2\text{H}_2\text{SO}_4 \rightleftharpoons 2\text{PbSO}_4 + 2\text{H}_2\text{O}$

Nickel-hydrogen	$2\text{NiOOH} + \text{H}_2 \rightleftharpoons 2\text{Ni(OH)}_2$
Primary (nonrechargeable)	
Leclanche dry cell	$\text{Zn} + 2\text{MnO}_2 \rightarrow \text{ZnO} \cdot \text{Mn}_2\text{O}_3$
Alkaline	$\text{Zn} + 2\text{MnO}_2 \rightarrow \text{ZnO} + \text{Mn}_2\text{O}_3$
Silver-zinc	$\text{Ag}_2\text{O}_2 + 2\text{Zn} + 2\text{H}_2\text{O} \rightarrow 2\text{Ag} + 2\text{Zn(OH)}_2$
Reuben mercury cell	$\text{HgO} + \text{Zn} + \text{H}_2\text{O} \rightarrow \text{Hg} + \text{Zn(OH)}_2$
Zinc-air	$\text{Zn} + \text{O}_2 + 2\text{H}_2\text{O} \rightarrow 2\text{Zn(OH)}_2$
Lithium-iodine	$2\text{Li} + \text{I}_2 \rightarrow 2\text{LiI}$
Lithium-sulfur dioxide	$2\text{Li} + 2\text{SO}_2 \rightarrow \text{Li}_2\text{S}_2\text{O}_4$
Lithium-thionyl chloride	$4\text{Li} + 2\text{SOCl}_2 \rightarrow 4\text{LiCl} + \text{S} + \text{SO}_2$
Lithium-manganese dioxide	$\text{Li} + \text{Mn(IV)O}_2 \rightarrow \text{LiMn(IV)O}_2$
Lithium-carbon monofluoride	$n\text{Li} + (\text{CF})_n \rightarrow n\text{LiF} + n\text{C}$

the phenomenon has been noted in $\text{Li/V}_2\text{O}_5$, Li/SOCl_2 , and other systems (Ref 6).

Secondary rechargeable batteries usually have considerably longer service lives than primary batteries. A much-used secondary battery is the lead-acid storage battery. A lead-acid battery consists of groups of positive and negative plates immersed in a concentrated electrolyte solution of sulfuric acid (H_2SO_4). The positive plates contain a web of lead alloy grids coated with lead dioxide (PbO_2). Negative plates contain a web of lead alloy grids coated with pure lead, usually known as sponge lead because of its porous nature. The following reactions occur during charging, and the reverse of these occur upon discharge (Ref 7–11):

Positive

Negative

During initial charging (first time), on the positive grid, a lead sulfate/lead oxide paste and a very small amount of the lead of the grid surface are converted to PbO_2 , providing good bonding to the grid. On the negative grid, the paste is merely converted to a pure lead sponge. The major corrosion problem in lead-acid batteries occurs during subsequent cyclic discharging and recharging. Overcharging can lead to further conversion of lead to PbO_2 on the positive grid, according to the reaction:

In general, the rate of this process is higher at lower acid concentrations (for example, 2.17 N, or 1.065 specific gravity) than at higher concentrations. It is necessary to design the grids such that corrosion of the positive grid is uniform rather than intergranular (Ref 12–19). Electric and hybrid vehicles use valve-regulated lead-acid cells that are subjected to dynamic operation with charge, rest, and discharge periods on the order of seconds. Such operation requires more sophisticated models that incorporate the electrochemical double layer to retard the corrosion process (Ref 20).

Fig. 1 Sites of corrosion in LiSO_2 batteries. SCC, stress-corrosion cracking

Alloys used to make grids include pure lead, lead-antimony with antimony levels from 0.5 to 6%, and, more recently, lead-calcium alloys. Pure lead has limited application as a grid material because it is extremely soft and prone to severe corrosion creep. However, to take advantage of the good corrosion resistance of the pure metal (better than the commonly used alloys), batteries for certain standby power applications have been designed to allow for creep (Ref 21, 22).

Corrosion of Fuel Cells

Corrosion of components in a fuel cell system is known to be a key factor in the reliability and service life of these systems. Fuel cells constitute a particular example of a battery where the two electrodes are not consumed during discharge but merely act as reaction sites for the reactants (fuel and oxidant), which are stored externally to the cell. The most common fuel is hydrogen, while air or pure oxygen is the most common oxidant. Many types of fuel cells have been developed, usually classified according to the type of electrolyte used. The five main types are:

- The phosphoric acid fuel cell (PAFC)
- The solid polymer electrolyte fuel cell (SPFC), where the electrolyte is a good proton-conducting fluoropolymer at 100 °C (212 °F)
- The alkaline electrolyte fuel cell (AFC), a relatively low-temperature system (80 °C, or 175 °F), which is used on the space shuttle as the principal power source
- The molten carbonate fuel cell (MCFC), which can operate on virtually any fuel due to its very high operating temperature of 1000 °C (1830 °F) (Ref 1)
- The solid oxide fuel cell (SOFC)

Two types of fuel cell technologies, PAFC and MCFC, are discussed here; the others are addressed in the article "Corrosion in Fuel Cells" in this Volume. Figure 2 shows a schematic of the repeating components of the PAFC power generation section (Ref 23). The PAFC operates under pressurized conditions that create a corrosive environment because of high operating temperatures and high water activity (Ref 24). The primary corrosion reactions are the anodic oxidation of the various allotropic forms of carbon and the dissolution of platinum (probably to form complexed platinum ion, Pt^{2+} , in solution).

Fig. 2 Schematic of the repeating components of the phosphoric acid fuel cell power generation section

The following generic cell reaction is representative of the carbon oxidation:

Extensive postmortem analyses have documented the corrosion-susceptible regions. Material loss, as a fraction of the material initially present, is greatest in the catalyst layer, followed by the losses in the substrate and then loss from the bipolar plate. This ranking is what would be expected based on relative surface area and extent of electrolyte wetting of the different components, assuming that the intrinsic corrosion resistance of each component is the same (Ref 25).

The MCFC component assembly follows the bipolar principle of the PAFC stack but uses completely different materials. Figure 3 shows the basic repeating elements in a MCFC stack. The electrolyte is a molten lithium carbonate (Li_2CO_3), potassium carbonate (K_2CO_3), and/or sodium carbonate (Na_2CO_3) mixture, with the most commonly chosen composition being 62 Li_2CO_3 -38 K_2CO_3 (usually referred to as a tile, because the carbonate salts and acuminate powder are hot pressed to form a solid piece). The ionic current in the cell is carried by the carbonate ion (CO_3^{2-}); therefore, the half-cell reactions at the anode and cathode are different from their PAFC counterparts. In this case, the cathode reaction is the reduction of oxygen by reaction with carbon dioxide (CO_2) to form CO_3^{2-} :

At the anode, hydrogen reacts with the CO_3^{2-} ion to form CO_2 and water:

The components subject to corrosion and the nature of the corrosion processes are reasonably well understood from postmortem analyses of tested cells. With type 316 stainless steel as the current collector, moderate-to-severe attack of the anode current collector was observed after a few thousand hours of operation, with much less attack observed at the cathode. The region of the current collector that was most severely attacked was the point of contact with the anode material

Fig. 3 Schematic of the repeating components of the molten carbonate fuel cell power generation section

(and thus in contact with the carbonate melt) and areas near the point of contact, probably owing to creep of carbonate onto the current collector (Ref 26).

A more serious and as yet unsolved corrosion process is the finding of significant solubility of NiO in the carbonate melts. Early theoretical analysis of metal corrosion in molten alkali carbonates presumed that NiO dissolution occurs by the reaction (Ref 27):

Work that addresses corrosion phenomena specific to MCFC technology is much less plentiful. The theoretical overview of the requirements for corrosion resistance in MCFC applications has served as a guide for much of the recent work (Ref 28). Recent work has been done to enhance the understanding of the predictions of the distributions of current density, water flux, corrosion, and membrane conductivity in fuel cells (Ref 29).

Corrosion in Fuel Cells

Prabhakar Singh and Zhenguo Yang, Pacific Northwest National Laboratory

AMONG ENERGY CONVERSION SYSTEMS being developed for using commonly available fossil and hydrocarbon-based fuels, fuel cells have attracted the most attention from utilities, automotive manufacturers, and military hardware designers. Desirable characteristics are (Ref 1, 2):

- Silent operation
- Ecological soundness
- Significantly high electrical conversion efficiency (up to 70% chemical to electrical)
- Modularity of construction (from a few watts to megawatts)
- Multifuel capability (coal-derived syngas, gaseous and liquid hydrocarbons)

Fuel cells also offer the ability to hybridize with gas turbines as well as the potential to develop near-zero-emissions power plants and to capture greenhouse gas from the exhaust, ultimately leading to a hydrogen economy and infrastructure. At present, widespread use of fuel cells is limited by high cost and their inability to achieve stable electrical performance and longer operational life. The cost per kilowatt from fuel cells can be five to six times that from conventional natural-gas-fueled turbines. To be commercially viable, fuel cells must also provide a lifetime of 5 to 10 years for stationary and automotive applications. This section addresses issues related to fuel cell electrical performance degradation and processes limiting the overall life of cells and stacks. Corrosion processes operating in a variety of fuel cell systems are presented and discussed, and corrosion mitigation schemes are highlighted. The understanding of corrosion processes in fuel cells is also expected to help in developing robust materials and a knowledge base for technologies such as electrolysis for the production of hydrogen, energy storage, and gas separation membranes.

Although the underlying science behind the fuel cell technology is well over a century old (invented by Sir William Grove in 1839), most technical and engineering progress in the development of integrated power systems is only a couple of decades old. Aggressive research and engineering development programs (R&D) worldwide have resulted in the development of commercial and prototypical precommercial

demonstration units for stationary, automotive, and military applications. The 100 to 250 kW (electrical kW) class fuel cell power plants are currently being deployed for the generation of both heat and power at industrial facilities. Smaller power plants are increasingly finding applications in automotive prime propulsion, auxiliary power, portable electronic devices, telecommunications, military hardware, and residential applications as a preferred power source and replacement for conventional internal combustion engines and batteries.

Fuel cells convert the chemical energy of gaseous or liquid fuels directly into electrical energy and heat via an electrochemical oxidation process. The absence of high-temperature combustion processes and an open flame front eliminates the formation of pollutants such as NO_x , volatile hydrocarbons, and particulate matter. Not limited by the Carnot cycle, fuel cells offer high chemical-to-electrical conversion efficiency. A fuel cell device is comprised of an anode electrode (exposed to fuel), a cathode electrode (exposed to oxidant), and a gas-impermeable electrolyte that separates the anode and cathode electrodes (Fig. 1). Electrolyte allows the passage of ions participating in the electrochemical oxidation. Fuel is oxidized at the anode electrode (production of electrons), whereas the oxidant is reduced (consumption of electrons) at the cathode electrode. While electrolyte allows for the transport of ions, electrons flow in the external circuit (load), producing electrical power. The fuel cell produces direct current electricity as long as fuel and oxidants are supplied. To build up a useful voltage, a series of cells are electrically connected and integrated into a stack. Commonly used fuels in conventional fuel cells are reformed gaseous and liquid hydrocarbons, hydrogen, coal-derived syngas, and liquid methanol. The commonly used oxidant is air. The theoretical cell voltage, called the open circuit voltage or Nernst voltage (V_{Nernst}), is governed by the chemical potential gradient in oxygen across the electrolyte and is given by:

$$V_{\text{Nernst}} = RT/4F \ln(P_{\text{O}_2 \text{ oxidant}}/P_{\text{O}_2 \text{ fuel}}) \quad (\text{Eq 1})$$

where R is the gas constant, T is the absolute temperature (K), F is the Faraday constant, and $P_{\text{O}_2 \text{ oxidant}}$ and $P_{\text{O}_2 \text{ fuel}}$ are partial pressures.

The actual operating cell voltage (V_{cell}) during a given current flow is reduced by ohmic losses ($V_{\text{ohmic}} = IR$), due to cell internal resistance (R), and by polarization losses ($V_{\text{polarization}}$), due to activation and mass transport:

$$V_{\text{cell}} = V_{\text{Nernst}} - V_{\text{ohmic}} - V_{\text{polarization}} \quad (\text{Eq 2})$$

The electrical output of a fuel cell is conventionally represented by a current-voltage relationship, shown in Fig. 2. At lower current densities, cell voltage drop is mostly associated with the activation or electron exchange process limitations (region 1), whereas at higher current densities, ohmic resistance (region 2) and mass transport (region 3) processes limit the overall performance. Degradation in the electrical performance and cell voltage loss with time are often attributed to corrosion and corrosion product formation and buildup, resulting in the poisoning of the electrode, localized metal loss, and development of resistive interfaces.

Fuel Cell Types

Review of recent technical literature indicates an explosive growth in the development and demonstration of fuel cell technologies, ranging from unconventional biological, direct carbon, and single-chamber fuel cells to engineering and scaleup of more conventional fuel cells. This section focuses on the “mature technologies,” which, depending on the operating temperature and type of electrolytes used, can be grouped into five major types (Fig. 3):

- Alkaline fuel cells (AFCs)
- Phosphoric acid fuel cells (PAFCs)
- Polymer electrolyte membrane fuel cells (PEMFCs)
- Molten carbonate fuel cells (MCFCs)
- Solid oxide fuel cells (SOFCs)

Alkaline fuel cells use a liquid alkaline electrolyte, such as KOH, and operate in the 100 to 250 °C (212 to 480 °F) temperature range. The liquid electrolyte transports OH^- , and the cell reactions are:

Fig. 1 Fuel cell. Fuel introduced at the anode is oxidized, and liberated electrons produce useful power in the external circuit.

Alkaline fuel cells have been successfully used in the National Aeronautics and Space Administration (NASA) Apollo and Orbiter space missions. When operated on pure H_2 and O_2 gases, AFCs show stable performance and relatively high power densities. However, cell performance significantly degrades during their operation on fuels and oxidants containing CO_2 (present as impurities in commercial reformed fuels and ambient air), due to the formation of solid carbonates (K_2CO_3). Presence of corrosive liquid hydroxides, electrolyte transport, and internal shorting also remain a concern for accelerated corrosion of conventional cell, stack, and the balance of plant components fabricated from low-cost commercial materials. For successful long-term operation of cells and stacks, it has been recommended that CO_2 must be scrubbed from both fuel and oxidant gas streams (Ref 3).

Phosphoric Acid Fuel Cells. As the name implies, PAFCs use proton-conducting phosphoric acid (H_3PO_4) as an electrolyte and operate in the 150 to 200 °C (300 to 390 °F) temperature range. Electrode reactions are:

The PAFCs most commonly use platinum or platinum alloy catalysts for electrode reactions. Highly dispersed catalysts are supported on carbon substrates that also act as a gas diffusion layer. The liquid electrolyte is constrained in a porous ceramic matrix. Bipolar (dual-atmosphere) gas separators and current collectors are fabricated from graphitic carbon with embossed patterns for fuel and oxidant flow. Stack designs incorporate provisions for cooling to remove heat produced during power generation. Although large commercial power plants employing PAFC stacks have been installed worldwide and have successfully operated on a variety of reformed hydrocarbon fuels, mass commercialization has not been achieved due to overall high system construction cost (>\$3000/kW). Limited life and performance degradation

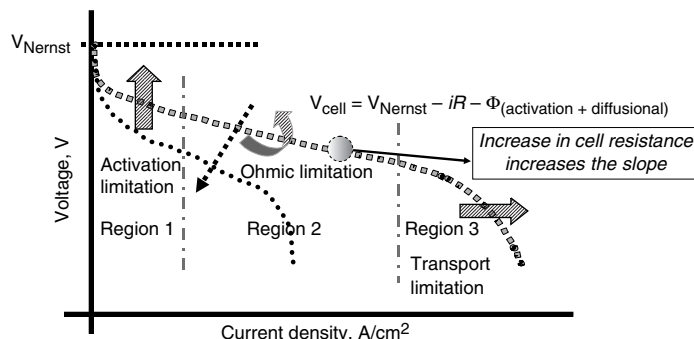

Fig. 2 Current-voltage characteristic of a fuel cell. Operating cell voltage is less than theoretical (Nernst voltage) due to activation (region 1), resistance (region 2), and mass transport (region 3). To improve output: in region 1, reducing activation polarization will move V-I curve upward; in region 2, reducing ohmic polarization reduces slope of V-I curve; in region 3, reducing diffusional polarization moves bend in V-I curve to the right. Degradation in electrical performance with time is attributed to electrode deactivation, electrode poisoning, and increase in cell resistance.

Fig. 3 Major fuel cell types currently under development for stationary, mobile, and portable applications. See text for fuel cell types. Source: Adapted from Ref 3

observed in the PAFC systems are attributed to electrode poisoning and catalyst deactivation due to gas-phase impurities (CO and H_2S), sintering and agglomeration of platinum, migration and evaporation of electrolyte, and corrosion of cell and stack component materials. Corrosion resulting in softening and large volume increases has been observed on bipolar graphite current collectors nominally prepared by the low-temperature carbonization (<1000 °C, or 1830 °F) process. Such bipolar plates, when carbonized at higher temperatures (>2500 °C, or 4530 °F), remain corrosion tolerant and retain their shape during long-term operation. Cell performance degradation mitigation strategies

have also been developed and implemented in commercial power plants.

Polymer electrolyte membrane fuel cells, also known as solid polymer fuel cells, have attracted attention in recent years due to increased interest in hydrogen and its potential application in automobiles as the prime propulsion power system (Ref 1–4). Automotive manufacturers in North America, Europe, and Japan have invested heavily in this technology to replace the internal combustion engine, with the intent of developing a hydrogen-base fuel infrastructure. The 50 kW and larger automotive power plants have been developed and installed in passenger cars and large public transport

buses. Similar power plants are also being field tested in stationary industrial power plants where hydrogen gas is readily available as a by-product of chemical processes (such as in the chlorine-alkali industry). The PEMFCs use a polymeric proton-conducting electrolyte and carbon-base electrodes containing noble metal and alloy catalysts for electrode reactions. Electrode processes for both oxidation of fuel and reduction of the oxidant are similar to the PAFC electrode processes. The PEMFCs nominally operate at 60 to 90 °C (140 to 194 °F) on high-purity hydrogen gas, because trace amounts of gas-phase contaminants such as CO, NH₃, and H₂S severely degrade the electrical performance due to the poisoning of cell electrodes. The presence of ammonia in the fuel stream and the formation of peroxides have been reported to react adversely with the membrane, limiting the overall life of the fuel cell. Due to lower operating temperatures, the cell electrodes and stack components remain prone to flooding with water and susceptible to galvanic corrosion. Conventional fuel cell stacks use graphitic molded bipolar gas separators and current collectors. Due to lower exposure temperature, such current collectors have been reported to resist corrosion. Metallic current collectors, coated with polymeric or metallic conducting coatings, have also been used in cell stacks for lightweighting and volume reduction. Care must be taken in developing crack-free or pinhole-free coatings to minimize localized corrosion (galvanic cell formation) and the release of metal ions that can contaminate the electrolyte membrane and poison the electrode catalysts.

Molten carbonate fuel cells operate in the 600 to 750 °C (1110 to 1380 °F) temperature range and use a variety of fuels, ranging from hydrocarbons to reformed hydrocarbon fuels (H₂, CO, CH₄, etc.), to produce electricity. Electrode reactions are:

It is noted that the cathodic reaction in MCFCs involves the presence of CO₂ gas. This is normally accomplished by taking the CO₂ from the used fuel stream. The MCFCs use a molten mixture of alkali metal carbonates as electrolyte for the transport of CO₃²⁻ ions participating in the anodic oxidation of fuel and the cathodic reduction of oxidant. The molten electrolyte, usually a binary mixture of lithium and potassium carbonate, is retained in a porous matrix sandwiched between an anode (nickel alloys usually containing chromium or aluminum to form respective internal oxides) and cathode (lithiated nickel oxide) electrodes. Gas separation and cell-to-cell connection is provided by conductive metal current collectors. Nickel-clad stainless steels (such as types 316, 310, Crutemp,

or 446) have commonly been used as the current collector where nickel is exposed to the fuel gas and stainless steel is exposed to the oxidant gas. Electrically insulating gas seals, called wet seals, are formed by aluminizing the metal substrates. Because of their higher operating temperature, MCFCs offer the potential for hybridization and higher electrical efficiency, high-quality product heat for combined heat and power applications, and fuel flexibility, including the use of hydrocarbons and internal reformation. The 250 kWe and MWe class power plants are currently being developed for distributed power generation, including industrial, military, and telecommunication remote power systems.

One of the primary shortcomings of the current technology is its lack of durability. High-temperature exposure, complex fuel and oxidant gas atmospheres, and the presence of molten carbonate electrolyte accelerate the corrosion and dissolution of oxides formed on the metallic current collectors and cathode electrode. The presence of bipolar exposure conditions also leads to a localized form of metal attack. Carburation and sensitization of the metallic substrates have also been observed during long-term tests in a carbonaceous gas environment. To enhance component life, the current R&D focus is on the selection of advanced materials compositions as well as the engineering design of components and the selection of operating conditions without compromising the electrical performance.

Solid oxide fuel cells operate at 600 to 1000 °C (1100 to 1830 °F) and use a solid-state electrolyte membrane for the transport of oxygen ion and electrochemical oxidation of fuels over a porous anode electrode:

In its most common form, SOFCs consist of a thin, dense film of doped zirconia electrolyte (such as yttria-stabilized zirconia) between a porous nickel cermet anode (Ni-ZrO₂) and a ceramic perovskite cathode (doped ABO₃, where A is a lanthanide group metal, and B is a transition metal) (Ref 5). Reactant flow and cell-to-cell electrical connection is achieved through metallic current collectors. High-temperature operation of the cells provides high-quality product heat, tolerance to poisons (sulfur, CO, and NH₃), ability to internally reform hydrocarbons on the cell electrode, hybridization with gas turbines, and significantly higher electrical conversion efficiency. The SOFC power generation systems ranging from several watts to several hundred kilowatts in size have been successfully assembled and field-tested.

Technology issues are currently being addressed by large industrial research projects as

well as by a number of U.S. government programs, including:

- Department of Energy: Solid-State Energy Conversion Alliance and Coal-Based Fuel Cell Systems programs
- Defense Advanced Research Projects Agency: Palm Power program
- Department of Defense: Tactical Quiet Generator and Unmanned Underwater and Aerial Vehicles programs

Some of the important development areas being addressed include identification and testing of advanced cell and stack component materials for improved electrical performance and performance stability. Although ferritic stainless steels and electronically conducting doped lanthanum chromites have been commonly used as current collectors, due to their matched coefficient of thermal expansion in intermediate- and high-temperature SOFCs, long-term stability issues remain. Accelerated corrosion, oxide evaporation, and contamination of electrodes are key development areas currently being addressed. Ferritic and austenitic stainless steel interconnects exposed to the bipolar environment show accelerated corrosion and localized metal loss. Chromia scale evaporation and subsequent condensation/interaction with cathode electrodes have also been observed. At 1000 °C (1830 °F), significant interaction of the anode electrode with silica vapor (originating from ceramic alumina-base thermal insulation) has been observed. Several advanced coatings, alloy formulations, and design modifications have been developed to mitigate such degradation.

Corrosion Processes in Fuel Cell Systems

The heart of the fuel cell power generation system is the fuel cell stack, where chemical energy of the fuel is efficiently converted into electrical power by the electrochemical oxidation process. To allow for the use of conventional fuels in cell stacks, efficient use of process heat, and conversion of direct current power into alternating current, the balance of the fuel cell power plant consists of fuel processor, heat exchangers, combustors, and power conditioner (Fig. 4a). The operating conditions in fuel cell power generation subsystems vary widely, depending on the nature of the fuel and the type of fuel cells used. Figure 4(b) shows the operating temperature range and exposure conditions for the fuel processor, fuel cell stack, and combustor. The introduction and presence of hydrocarbon fuel gas mixtures near the inlet of the fuel processor develops higher carbon activity in the fuel processor. As the hydrocarbons reform to produce H₂ and CO mixtures along the flow direction, hydrocarbon and steam partial pressures reduce. Exposure conditions in the cell stacks, on the other hand, lead to the consumption of H₂, CO, and CH_x fuel species and the

production of H_2O and CO_2 along the fuel flow direction. Formation of H_2O and CO_2 in the gas stream and reduction in the $\text{H}_2/\text{H}_2\text{O}$ and CO/CO_2 ratio also gradually increase the oxygen partial pressure in the fuel stream near the fuel outlet. The exiting fuel from the cell stack is conventionally recirculated and fed to the reformer or fully combusted to produce thermal energy before its safe release into the environment.

Corrosion processes in fuel cells are divided into three major groups:

- Corrosion due to solid-gas interactions
- Corrosion due to solid-liquid interactions
- Corrosion due to solid-solid interactions

Corrosion due to solid-gas interactions represents a wide variety of corrosion processes that range from oxidation, carburization, and metal dusting, to surface oxide evaporation and bipolar corrosion during exposure to gas-phase reactants and simultaneous exposure to an oxidizing (oxidant) and a reducing environment (fuel). Oxidation of metals and alloys in simple

and multiconstituent gas atmospheres is well studied and documented. The classic metal oxidation and surface oxide buildup mechanism developed initially by Wagner (Ref 6) obeys the parabolic time law, and the rate-limiting steps are controlled by the diffusion of ions in the oxide lattice. Electrical neutrality in the growing scale is maintained by the diffusion of electrons in the same direction as the cations, and local equilibrium is maintained throughout the scale. The oxidation mechanism has been further extended (Ref 7–9) to account for the oxidation of alloys, internal oxide formation, transition from internal to external oxidation, complex oxide buildup in multioxidant systems, and oxide growth due to the molecular transport of reactants within the growing scale. The oxidation of iron- and nickel-base chromia- and alumina-forming alloys and the role of alloying constituents on the development of protective oxides have been studied (Ref 9–13). Oxide scale morphology predominantly depends on the exposure temperature and chromium level. At lower chromium levels ($<5\%$), both iron and

nickel alloys form mixed oxides and often show acceleration in the oxidation rate, whereas at 10 to 12% Cr level, alloys initially show the formation of protective surface oxides. Long-duration exposures of such alloys lead to internal oxidation and formation of a chromium-depleted zone near the surface. At chromium levels >15 to 18%, the alloys form a protective chromia scale and also are capable of rehealing (due to a higher chromium reservoir) in the event of scale spallation and cracking.

The addition of rare earth elements, such as zirconium, yttrium, and hafnium, to bulk alloys has proven beneficial in improving the scale adherence under thermal cyclic conditions. Rare earth additions facilitate the formation of anchors at the metal-oxide interface and also provide vacancy sink (annihilation and prevention of pores) for improving the adherence of the oxide with the metal substrate (Ref 14, 15). For applications where electrically conductive oxides are required in order to minimize the resistive loss, alloys are tailored to reduce the concentrations of elements such as silicon and aluminum. Silicon present in the alloy has a tendency to segregate and form continuous SiO_2 at the scale-metal interface and increase the electrical resistance of the scale. At certain levels, aluminum also tends to form alumina at the metal-oxide interface, increasing the overall scale resistance. It should, however, be noted that the additions of aluminum and silicon improve the scaling resistance and hence are selectively used where the electrical conduction in the scale is not an important requirement. Oxidation of metals and alloys in a complex gas environment has been extensively studied for its importance in understanding the scaling process and materials selection for applications in cell and stack components and fuel processors exposed to a reducing gas environment. The presence of an environment consisting of H_2 , CO , CH_4 , CO_2 , H_2O , and so on establishes scaling processes very different from simple oxidation in oxygen or air. Such exposures have the potential to form condensed products from reactions with carbon, oxygen, and so on. Metals such as nickel and copper remain stable in most fuel environments and up to 99% fuel utilization. Experiments conducted on commercial Ni-200 foil samples in N_2 -3% H_2 -3% H_2O for 200 h showed thermal grooving of the metal surface at 800 and 1000 °C (1470 and 1830 °F). Cross-sectional analysis of the metal showed no surface oxide formation. Grain boundaries of the samples were, however, found to be decorated with SiO_2 . Molecular transport of gaseous species and the establishment of redox (H_2 - H_2O and CO - CO_2) reactions within the oxide scale enhance the scaling and localized metal loss. It is also observed that the presence of CO and $\text{CO}-\text{CO}_2$ redox couples facilitates the carbide formation at the metal-scale interface.

Long-duration exposures of both austenitic and ferritic stainless steels during the operation of molten carbonate fuel cells have confirmed such observations, showing significant

chromium carbide formation at the metal interface (Ref 16). At 600 to 700 °C (1110 to 1290 °F), carbide formation within the bulk metal, especially along the grain boundaries, also occurs due to sensitization. Carburization of stainless steels in high- ($a_c = 10^{-1}$) and low- ($a_c = 10^{-20}$) carbon atmospheres was examined in the 600 to 700 °C (1110 to 1290 °F) temperature range, and it was found that carbides can form by both molecular transport and solution diffusion processes in high-carbon-activity environments, whereas carbide formation is expected only by molecular transport in low-carbon environments. Establishment of a redox gas atmosphere within the oxide enhances the metal ion transport by short circuit diffusion, leading to thicker scale growth and underlying metal loss. Stainless steels (types 304 and 316) form a multilayer scale, where the outer scale is comprised of iron oxide and the inner scale predominantly consists of porous chromia and nickel. At higher concentrations of chromium (24 to 26%) and nickel (>20%) in type 310, the scale morphology changes considerably, forming uniform outer and inner oxide layers, followed by a nickel-enrichment layer in the metal near the metal-oxide interface. To minimize carbide formation and sensitization, common practice involves the use of low-carbon bulk alloys. Ingress of carbon through the scale is also minimized by reducing the molecular transport and forming defect-free oxides at the surface. In the presence of hydrocarbons, both nickel- and iron-base alloys remain susceptible to carbon deposition and metal dusting. Nickel-base chromia-forming alloys perform better than iron-base alloys under SOFC conditions, because the oxide scale, consisting of Cr_2O_3 (formed on nickel-base alloys), provides better protection than spinel-containing scales formed on iron-base alloys. Metal dusting is accelerated in low-humidity and high-pressure environments and can occur more frequently near the fuel inlet. Carbon formation in the nickel anode and catalyst also remains a concern during fuel cell operation. Gaseous reactions that lead to metal dusting are:

The mechanisms of metal dusting have been studied and discussed (Ref 17–19). Factors influencing metal dusting include carbon activity in the gas stream, oxide morphology and composition, temperature, and exposure time. Degradation of nickel due to carburization and metal dusting has been frequently observed in the reformer and also on the cell anode under upset operating conditions, where filamentary carbon forms at the substrate and breaks the integrity of the support. Large volume changes associated with the carbon formation result in pressure buildup in the reformer and cell stack. At elevated temperatures (600 to 1000 °C, or

1110 to 1830 °F), representative of high-temperature solid oxide and molten carbonate fuel cells, oxide evaporation also becomes a concern for long-term metal substrate protection. Evaporation of chromia and silica are especially of interest, because they not only relate to the oxide loss from the scale surface but also the contamination of electrodes and electrical performance loss. Evaporation of chromia and formation of CrO_3 vapor phase above 1000 °C (1830 °F) in air is well documented in superalloy literature (Ref 10). At intermediate temperatures and in the presence of water vapor, chromia also forms hydrated oxides that have higher vapor pressure than CrO_3 (Ref 20, 21):

Evaporation of chromia results in the deviation of the scale growth kinetics from parabolic to parabolic rates. Evaporation reactions and vapor pressures of chromium oxyhydroxides are shown in Fig. 5. Vapor species formed at the scale surface migrate along the reactant flow direction and have the potential to react and poison the contacting electrode. Like the accelerated evaporation of chromia in an oxidant gas environment, silica evaporation has also been reported in a SOFC reducing (fuel) environment containing steam. At 1000 °C (1830 °F), gaseous hydrated silica vapors form according to the following reaction:

The silica vapor entrains in the fuel gas deposits, poisoning the nickel electrode and hydrocarbon reforming catalyst (Ref 22). Silica transport in SOFCs has been studied (Ref 23), and mechanisms of vaporization, transport, and deposition over nickel reforming substrates have been identified. A bipolar exposure (air/metal/ H_2 - H_2O) condition results from simultaneous exposure to an oxidizing (cathodic) and reducing (anodic) environment and is typical of cell interconnects and gas separator exposure. Long-term electrical tests in MCFC and SOFC power generation systems showed accelerated corrosion, metal loss, and bulk structural changes on interconnects and gas separators. A few citations exist in the literature concerning corrosion under bipolar exposure. One of the earlier reports (Ref 24) indicated unusual oxidation and metal loss during the oxidation of several stainless steels under MCFC operation conditions. Simple oxidation in oxidizing or reducing gases was not able to explain such degradation. Recently, the bipolar exposure conditions were simulated, and the corrosion behavior of candidate current collector materials silver, iron alloys, and nickel alloys were investigated (Ref 24–27).

Although silver remains stable in oxidant and fuel gas atmospheres, bipolar exposure resulted in bulk porosity formation and cracking. Figure 6 shows the micrographs of silver exposed to

flowing air and fuel (H_2 -3% H_2O). Dissolution of both hydrogen and oxygen in the bulk metal and their subsequent reaction form high-pressure water vapor at locations such as grain boundaries and other nucleation sites. This mechanism results in the formation of interconnected porosity and cracks (Fig. 7). The thermodynamic models (Ref 25) of the reactions and associated Gibbs free energies (ΔG_n) are:

The net energy balance is:

$$\Delta G_4 = \Delta G_1 + \Delta G_{2v} + \Delta G_3$$

$$\log K_4 = \log (P_{\text{H}_2\text{O}}) - 2 \log (a\text{H}) - \log (a\text{O})$$

$$\log (P_{\text{H}_2\text{O}}) = -\Delta G_4/4.575T$$

$$+ 2 \log (a\text{H}) + \log (a\text{O})$$

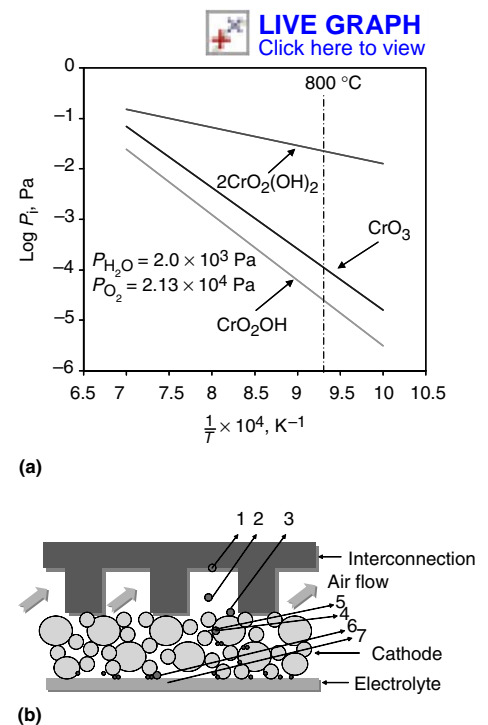

Fig. 5 Chromia scale evaporation in an oxidizing environment. (a) Partial pressure of various gaseous species formed in humidified air. Chromia evaporation is dominated by $\text{CrO}_2(\text{OH})_2$ formation, especially at low temperatures (note inverse temperature scale). At 800 °C (1470 °F), for example, partial pressure of $\text{CrO}_2(\text{OH})_2$ is 220 times greater than CrO_3 . The level of $\text{CrO}_2(\text{OH})_2$ gas is still significant at 800 °C (1470 °F) and 0.022 Pa (3.2×10^{-6} psi), which is 52% of the pressure at 900 °C (1650 °F). (b) Schematic presentation of possible formation, transport, and interactions of chromium species during solid oxide fuel cell operation near the cathode. 1, chromium evaporation from interconnection surface; 2, gas-phase transport of chromia vapor; 3, contact with cathode surface; 4, reaction with cathode; 5, diffusion into cathode; 6, reduction and deposition at cathode/electrolyte interface; 7, diffusion into electrolyte/barrier layer

where K_4 is the equilibrium constant, $P_{\text{H}_2\text{O}}$ is the partial pressure of H_2O , T is absolute temperature (K), and a_{H} and a_{O} are activities of hydrogen and oxygen. The relation of temperature

to the partial pressure of H_2O formed in bulk silver is:

Temperature, K	$\log(P_{\text{H}_2\text{O}})$, atm
600	17.05
700	14.15
800	11.97
900	10.29
1000	8.92

These values of steam pressure remain high in the operating temperature range.

Similar experiments conducted on types 304 and 430 stainless steels showed localized scale growth and underlying metal loss (Fig. 8, 9) (Ref 26–28). Similar scale morphology has been reported to develop during the oxidation.

Similar scale morphology has been reported to develop during the oxidation of stainless steels in steam-containing environments (Ref 29, 30). Exposure of nickel and nickel alloys to similar bipolar exposure conditions only slightly modified the scale morphology and the scaling rate. Although the exact mechanism of the acceleration in corrosion observed on stainless steels under bipolar exposure is not fully understood, it is hypothesized by the authors that the diffusion of hydrogen through the metals from the fuel side to the oxidant side could result in the H_2 - H_2O redox reaction at the metal-oxide interface at the oxidant side, leading to accelerated outward diffusion of cations in the oxide scale and localized growth of oxide nodules. Schematic presentation of the reaction processes is shown in Fig. 10. In the presence of steam, it is postulated that the localized defects present in the scale lead to the inward diffusion of H_2O , the possible development of H_2 - H_2O redox atmosphere, and the outward migration of cations. The observed acceleration in the oxidation can also occur due to the modification of oxide stoichiometry and changes in the scale defect structure or the transport of protons through the scale. Further work is needed to understand the role of the

forementioned processes and bipolar exposure on the scaling behavior.

Corrosion due to Solid-Liquid Interactions. The presence of reaction product, such as liquid water in PEMFCs and liquid electrolytes in PAFCs, AFCs, and MCFCs, creates the potential for enhanced corrosion and for corrosion processes different than the solid-gas interactions previously presented. Corrosion processes in the presence of liquids vary from simple galvanic, to complex oxide dissolution and metal pitting, to hot corrosion where accelerated metal corrosion is controlled by the basicity or acidity of the melt. All forms of corrosion tend to accelerate the localized metal loss. At lower temperatures in PEMFCs, for example, the formation of liquid water corrodes the metal bipolar plates and contaminates the electrodes and catalysts. In PAFCs, the liquid phosphoric acid tends to corrode the carbon electrodes and current collectors, whereas in MCFCs, the molten carbonate electrolyte dissolves oxides formed on both current collectors and seals and develops nonprotective scale.

Corrosion in the presence of water formed by the oxidation of hydrogen has been studied in PEMFCs (Ref 31–33). The PEMFC environments comprise weakly acidic media and are often found to be corrosive to the stack components, in particular, cell-to-cell interconnects, that are made from either graphitic carbon-base materials or stainless steels. The carbon/graphite-base materials show promise in the chemical stability required to withstand the high-humidity and low-pH environment of the PEMFC stack, whereas metal bipolar plates suffer from surface oxide formation. Metal ions (e.g., Fe^{n+}) leaching from the metallic interconnects into the polymer membrane block the sulfonic acid sites and reduce the ionic conductivity of the membrane. Passivating oxides or oxyhydroxide layers formed on the surface of the metallic interconnects also increase the contact resistance between the bipolar plate and electrodes, resulting in long-term performance loss. The metal ions also poison the electrode catalysts, leading to degradation in cell performance. To protect the metallic interconnects and prevent metal ion poisoning to the polymer membrane, a thin, inert, yet electrically conductive coating is often applied onto the metallic interconnects, using various surface-coating techniques. Both precious metals (e.g., gold) and conductive oxides (e.g., SnO_2) have been successfully used as the coating materials. A great level of success has been reported with the precious metal coatings. Overlay oxide coatings appear to be acceptable in terms of cost but have thus far not proven sufficiently viable due to the formation of pinhole defects, which can result in local galvanic corrosion and metal ion contamination to the membrane (Ref 34). The presence of pinholes has been reported to be mitigated via the application of an interlayer between the metal and an overlay coat (Ref 35, 36). For example, the combination of an electroless nickel interlayer and a physical vapor deposited CrN outer layer

Fig. 6 (a) and (b) Microstructural cross sections of silver tubular sections, and (c) and (d) surfaces. (a) and (c) were exposed to a bipolar condition ($\text{H}_2 + 3\%\text{H}_2\text{O}/\text{silver}/\text{air}$) at 700°C (1290°F) for 700 h. (b) and (d) were exposed to air at the same temperature and duration. (c) Grain-boundary porosity is present. (d) No grain-boundary porosity

Fig. 7 Schematic presentation of porosity formation and structural degradation in silver exposed to hydrogen/air dual environment. Partial pressure of steam formed within the bulk metal remains very high at all exposure temperatures.

exhibited a better corrosion resistance than the CrN layer only (Ref 35). In addition to CrN, other transition metal nitrides as well as their carbides appear to offer a combination of high electrical conductivity and good corrosion resistance that makes them attractive for potential use as a protective surface layer in this application. Recent work has shown promise with thermally nitrided metal surfaces (Ref 37, 38).

Corrosion of metallic components in the presence of molten carbonate electrolyte mixtures (usually lithium and potassium carbonate eutectic) has been the subject of intense study during the development of materials for MCFCs. Scaling of both iron- and nickel-base alloys has been extensively studied in both anode and cathode gas atmospheres (Ref 39). Experiments in the anode gas showed the precipitation of iron oxides at the electrolyte-gas interface, indicating scale dissolution and precipitation-type fluxing reaction. The molten electrolyte does not show any presence of chromium. In the case of chromium-plated steels, the highest protection is achieved due to the formation of reaction products consisting of Cr_2O_3 and LiCrO_2 . The scale

formed is 20 to 30 times thinner than those formed on the stainless steels. Chromium plating also offers a barrier to carbon diffusion and carburization of the metal substrate. The oxidation resistance of Al_2O_3 -forming alloys remains excellent in the presence of molten electrolyte; however, the alloys provide highly electrically resistive scale not suitable for electrical conduction. Nickel-clad or copper-plated stainless steels showed the stability of nickel and copper in the fuel gas. The process of oxide scale fluxing in the molten electrolyte mixture in the fuel gas is considered identical to the hot corrosion fluxing mechanisms proposed (Ref 40).

In the cathode gas atmosphere, stainless steels do not show fluxing of the oxides. The electrolyte, however, dissolves surface Cr_2O_3 and other oxides to form dissolved species such as CrO_4^{2-} , FeO^{2-} and NiO^{2-} . Figures 11 and 12 present the corrosion processes operating in the anode and cathode gas atmospheres. The relative amount of dissolved species depends on the oxide melt equilibrium. Thermodynamic calculations indicate that the ratio of CrO_4^{2-} to FeO^{2-} is very high in the cathode gas, indicating preferential dissolution of Cr_2O_3 from the scale. The Cr_2O_3

dissolution and formation of chromates is:

Dissolution of Cr_2O_3 and its higher solubility in the electrolyte make the chromium plating a poor choice for cathode-side application. Alloys forming exclusive corrosion products, such as SiO_2 , MnO , $(\text{Mo}, \text{V}, \text{or W})_x\text{O}_y$, also show excessive dissolution in the electrolyte. Dissociation and consumption of carbonate melts lead to permanent loss of the electrolyte from the fuel cell system. Formation of hydroxides (reactions with H_2O) also increases the loss of the electrolyte. Loss of the electrolyte from the cell increases cell resistance and electrical performance degradation. The MCFC wet seal area that separates the fuel, air, and ambient atmosphere experiences accelerated corrosion in the presence of molten electrolyte because of the development of localized corrosion cells during simultaneous exposure to reducing and oxidizing atmospheres. Aluminizing of the metal surface has demonstrated corrosion prevention due to the formation of a passivating alumina scale (Ref 41).

Corrosion due to Solid-Solid Interactions. Solid-solid interactions in fuel cells have been most frequently associated with high-temperature solid-state reactions where adjacent components of the cell stack or subsystems react to form undesirable corrosion products and

structures that limit the performance and life of the fuel cell system. Such interactions vary from Kirkendall void formation due to interdiffusion of metals to compound formation near the electrode-electrolyte interfaces. Interdiffusion of metals leading to Kirkendall void formation has

been observed during the corrosion evaluation of copper plating in the fuel gas environment of MCFCs (Ref 42). Copper plating that is thermodynamically stable under the anode environment shows extensive diffusion in the contacting nickel anode, resulting in the formation of large porosity in copper and swelling in nickel. Higher diffusion of copper in nickel leads to net positive flow and transport of copper and formation of voids in the coating layer. Diffusing copper in nickel forms a nickel-copper alloy. Solid-state interdiffusion has also been observed in nickel plating and aluminized coatings formed over stainless steels. In SOFCs, the most commonly observed solid-solid interactions represent reactions between interconnects and electrodes. One such reaction is the formation of resistive pyrochlore ($\text{La}_2\text{Zr}_2\text{O}_7$) at the perovskite (doped LaMnO_3) cathode electrode and yttria-stabilized zirconia electrolyte interface:

Reduced oxygen partial pressure favors the forward reaction, whereas the presence of MnO favors the backward reaction and dissolution and removal of the pyrochlore. Reactions of the perovskite cathodes with the interconnect surface oxides, such as Cr_2O_3 , Al_2O_3 , SiO_2 , and FeO , also result in the formation of discrete compounds such as LaCrO_3 and LaSiO_3 . Substitution of the cations present in the surface oxides also modifies the electrical properties of the cathode. For ceramic chromite interconnects, prolonged exposure to elevated temperatures shows interdiffusion of manganese from the cathode electrode and the formation of interface porosity. Optimization of the interconnection chemistry (doping of both A and B sites) and lowering of the fabrication and cell operation temperatures reduce such interactions. In the SOFC seal area, similar solid-state reactions involving surface chromium oxide (formed on the current collectors) and glass result in the formation of chromates (Ref 43).

Materials and Technology Status

Global interest in the development and deployment of fuel cell power generation systems has considerably increased in the last decade. As the major fuel cell technologies (PEMFCs, MCFCs, and SOFCs) mature and transition from laboratory to commercial products, R&D efforts focus on the long-term performance stability, development of chemically and structurally compatible component materials, and understanding of long-term degradation processes. Efforts range from the optimization of engineering design that can allow for the mitigation of hot spots and thermal stresses, to the development of bulk materials and surface coatings for minimizing corrosion, to the development of operating conditions that successfully eliminate or reduce undesirable transients (changes in temperature, environment). To

Fig. 10 Mechanism for the development of scale under the bipolar condition

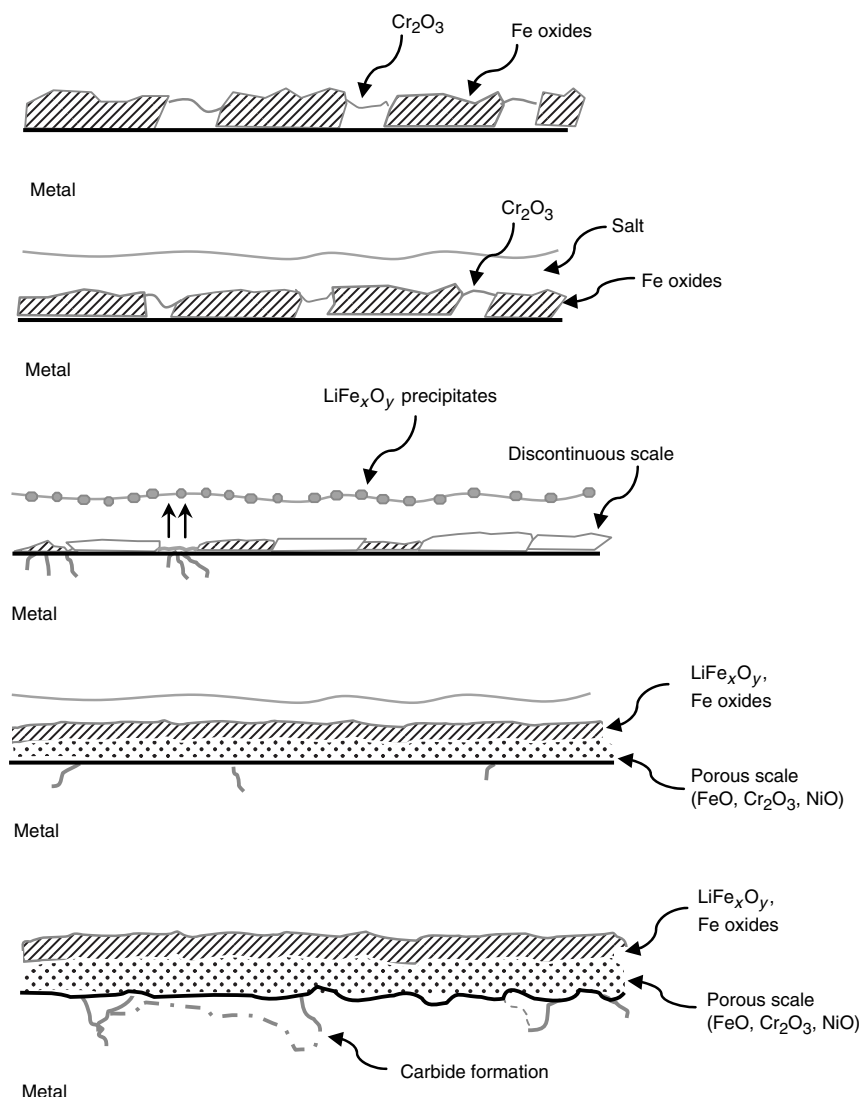

Fig. 11 Representation of scale growth in the anode atmosphere of the molten carbonate fuel cell. Time progresses from top to bottom. Oxide fluxing is observed during the oxidation of stainless steels.

remain cost-competitive, the development activity also focuses on lower-cost materials and the fabrication process.

The PEMFCs are widely recognized as the most viable fuel cell technology for vehicle prime propulsion. While significant advancements have been made over the past several years in improving the electrical performance of the PEMFC, the current focus on technology development is geared toward improvement in system life, performance stability, and cost reduction. From a corrosion perspective, the key development areas that are worthy of mention are the development of bipolar plate materials, corrosion-resistant coatings, and corrosion inhibitors for the coolant systems. Because the state-of-the-art bipolar plate is the most bulky component in the PEMFC stack and one of the most expensive to manufacture, a significant effort is underway in the development of lightweight and chemically stable materials and coatings. Overall, the bipolar plates are made from either a carbon- or a metal-base material. While the carbon-base materials, particularly carbon-carbon and carbon-polymer composites, offer the chemical stability required to survive the high-humidity and low-pH environment of the PEMFC stack, these materials usually require complex manufacturing processes and are therefore quite expensive to manufacture. On the other hand, metallic bipolar plates can be manufactured in very thin form (150 to 250 μm , or 6 to 10 mils) to reduce weight and volume in the overall stack and can be mass-produced in the desired shape, using inexpensive stamping or embossing processes. The key challenge with metal interconnects is surface corrosion. A number of approaches employing surface coatings are currently being studied. Although the greatest level of success has been achieved with noble metal coatings such as gold and palladium, the coating process remains prohibitively expensive. Transition metal nitrides and carbides offer a combination of high electrical conductivity and good corrosion resistance that make them attractive for potential use as a protective surface layer in this application (Ref 38). While recent work has shown promise with thermally nitrided metal surfaces and the development of pinhole-free coatings, the research is focused on developing alloys that not only can be uniformly nitrided for corrosion resistance and electrical conduction but also exhibit mechanical properties suitable for net shape forming. Because the exposed metal surfaces in the cell and stack cooling systems consist of a variety of ferrous and nonferrous alloys, such as stainless steel, aluminum, copper, and so on, there is a need for the development of inhibited coolant that minimizes corrosion and also remains compatible with the electrical requirements. Coolants with both metallic and nonmetallic additives are also being developed to meet the electrical conductivity (lower conductivity and hence lower shunt current), heat capacity (higher heat capacity), and thermal conductivity (higher thermal conductivity) requirements.

The MCFCs. Recent R&D focus centers around the development of cost-effective and corrosion-tolerant cell, stack, and balance of plant materials to improve the overall system life. Component designs, chemistry, and fabrication processes are some of the key areas currently being addressed. Cell operating

conditions, including nominal and off-design conditions, are shown in Table 1. Because on-anode use of hydrocarbon fuels has proven highly effective in improving the electrical efficiency and thermal management of the stack, there remains significant interest in assessing the material stability under hydrocarbon exposure

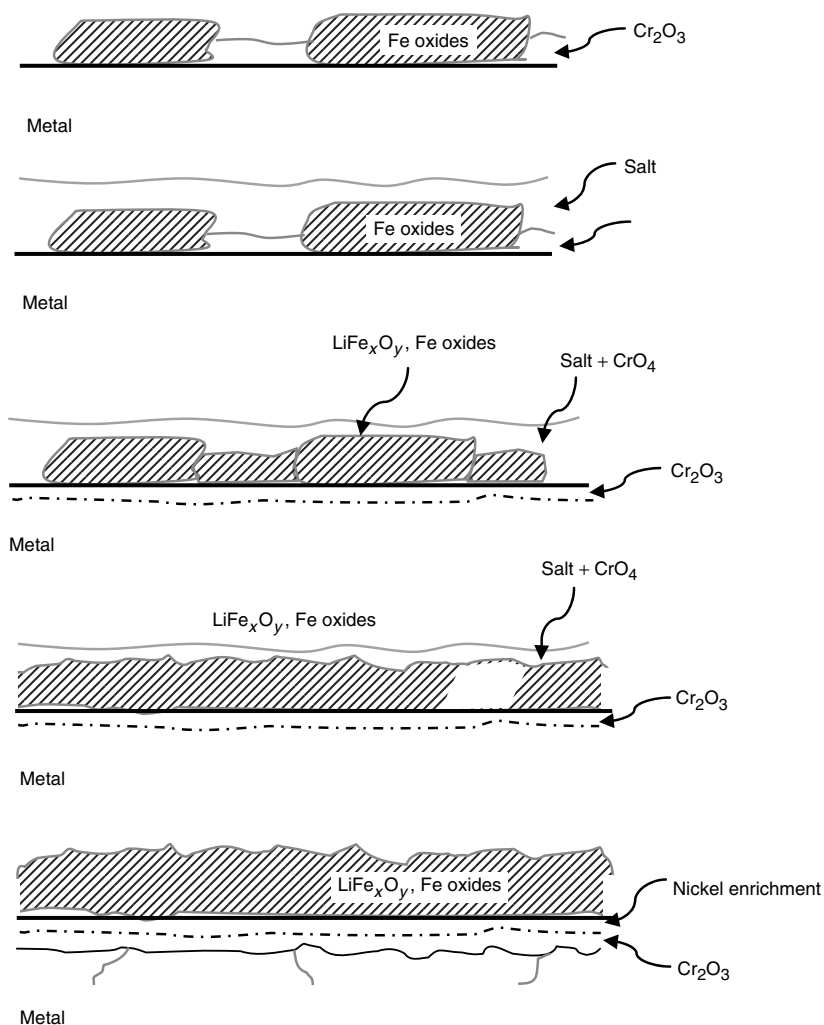

Fig. 12 Representation of scale growth in the cathode atmosphere of the molten carbonate fuel cell. Time progresses from top to bottom. Oxide dissolution is observed during the oxidation of stainless steels.

Table 1 Operation parameters of molten carbonate fuel cells and their impact on corrosion

Operation parameters	Operating range	Impact on corrosion
Normal		
Fuel gas	Low- and medium-Btu coal gas	Affects hydrogen diffusion rate and extent of corrosion
Oxidant gas	Air, 5–10% CO ₂	May affect soluble corrosion products formation
Contaminants	1–3 ppmv H ₂ S 20–40 ppbv SO ₂	May cause intergranular corrosion, enhanced corrosion
Temperature	600–750 °C (1110–1380 °F)	High-temperature-enhanced corrosion
Pressure	1–10 atm	May lead to increased carburization
Fuel utilization	0–75%	Higher utilization may result in higher corrosion.
Oxidant utilization	0–50%	Minor effects expected but not characterized
Thermal cycling	>10 cycles	Severe corrosion due to cracking
Off-design conditions		
Fuel utilization	~100%	May result in cracking of protective scale, severe corrosion
Oxidant utilization	~100%	Not known
Electrolyte	Flooded	Excessive fluxing of corrosion layer

Table 2 Comparison of nickel-base alloy and ferritic stainless steel properties relevant for solid oxide fuel cell interconnection

Property	Nickel-base 230(a)	Stainless steel(b)
Composition	Ni-22Cr-14W-2Mo-0.5Mn	Fe-22Cr-0.5Mn
UNS No.	N06230	...
Coefficient of thermal expansion, $10^{-6}/K(c)$	15.2	12.2
Oxidation resistance, $10^{-13} g^2/cm^4 \cdot s$		
At 700 °C (1290 °F)	0.05	2.0
At 800 °C (1470 °F)	0.36	7.0
Surface resistivity, $m\Omega cm^2$		
At 700 °C (1290 °F)	5.0	4.0
At 800 °C (1470 °F)	10.0	9.0
Ultimate tensile strength, MPa (ksi)		
At room temperature	865 (125)	443 (64)
At 760 °C (1400 °F)	605 (88)	<100 (15)
Corrosion resistance, dual atmosphere	Enhanced formation of uniform chromia scale	Grow hematite to accelerate attack
Manufacturability	Easy	Easy
Raw material cost	Fairly expensive	Fairly expensive

conditions. Processes such as carburization and metal dusting are being studied in depth to understand long-term impact on the breakdown of the protection offered by growing surface scale. The role of claddings and alloy compositions is being examined to minimize carbon ingress in the bulk metal. The sensitivity of nickel cladding toward substrate carburization is also a topic of research. Another area of research includes electrolyte management and protection of metals under the wet seal. Means of controlling the amount of the electrolyte in contact with exposed metal surfaces are being examined as a means of controlling the hot corrosion fluxing of the oxide. Oxide dissolution and contamination of the lithiated nickel oxide also depend on the extent and type of oxide dissolved in the molten electrolyte. At the systems level, R&D focus areas cover high-temperature heat exchanger and reformer materials.

The SOFCs. Materials research in SOFCs has steadily progressed in the areas of electrodrics, electrolyte materials development, and optimization of ceramic processing techniques. A thrust toward the development of intermediate-temperature SOFCs has resulted in expanded efforts in the areas of metallic current collectors and protective coatings development (Ref 44, 45). Table 2 shows the properties of a typical iron- or nickel-base alloy of interest to SOFC developers. Until recently, the leading material for interconnect was doped lanthanum chromite ($LaCrO_3$), a ceramic that could easily withstand the traditional 900 to 1000 °C (1650 to 1830 °F) operating temperature. The high cost of raw materials and difficulties in obtaining high-density chromite parts at reasonable sintering temperatures has led to efforts toward the development of low-cost iron-base alloys and appropriate coatings for applications in the 600 to 800 °C (1110 to 1470 °F) temperature range. Ferritic alloys, such as chromia-forming ferritic stainless steels, demonstrate a close thermal expansion matching to ceramic electrodes. Research efforts on advanced alloy formulations as well as simple metallic systems such as nickel

and silver are being pursued to understand oxidation processes in anode and cathode gas and also under bipolar exposure conditions. Corrosion in seals and optimization of sealing materials have also attracted considerable attention in recent years. A wide variety of seal designs (compressive, compliant, rigid, self-healing) and materials are currently being investigated. At the system level, the need to develop corrosion-tolerant heat exchanger and reformer materials has been identified.

Automotive Body Corrosion

D.L. Jordan and J.L. Tardiff, Ford Motor Company

CORROSION is a process defined as the reaction of a material with its environment. Corrosion behavior is controlled by the susceptibility of the material, the aggressiveness of the environment, and the effectiveness of any intervening barrier meant to keep the material and environment from interacting.

The materials used in as-produced automobile bodies are relatively straightforward to identify or characterize. Steel, with zinc and zinc alloys applied as sacrificial coatings, currently is the predominant metallic material for automotive body panels and structures. Aluminum, stainless steel, metallic and metallic-coated fasteners, and metallized plastic trim materials all are common and must be considered when developing the overall corrosion protection strategy. A variety of highly engineered and well-characterized paints and organic sealants are used as barrier coatings.

On the other hand, the automotive operating environment is not so simple to characterize. The use of road deicing salts, mainly sodium chloride, in North America has increased tenfold since the 1950s and varies dramatically among different geographical regions and within different state road jurisdictions. Some locales use combinations of sodium chloride, calcium chloride, magnesium chloride, and other potentially corrosive chemical deicers (Ref 1). Dust-control practices in rural areas frequently include the use of corrosive hygroscopic chemicals such as calcium chloride. The type and amount of air pollution varies with time and location. Driving and maintenance behaviors vary dramatically among the driving populace, and commercial car washes introduce a variety of chemicals that can beneficially or detrimentally affect the corrosion performance of the vehicle. Indeed, even the atmospheric component of the automotive environment varies dramatically with geographical location. Consequently, the environment to which a vehicle is exposed varies widely and can be expected to engender a variety of corrosion types and corrosion rates.

Exposure of known materials to an ever-changing environment results in the formation of possibly unique soluble and insoluble corrosion products that can influence subsequent corrosion reactions and rates. Automotive engineers are

charged with providing vehicles that are resistant to the corrosive effects of all commonly encountered environmental input, even if a given vehicle may never be exposed. In view of the likelihood that little can be done by the vehicle manufacturer to control the environment in which a motor vehicle is operated, the general strategy is to provide a cost-effective and production-friendly combination of corrosion-resistant materials and barrier coatings.

The likely futility of forecasting corrosion lifetimes of materials in such a dynamic and operator-specific environment was described more than a generation ago when LaQue wrote, "There is no chance whatsoever of coming up with a test by which so many hours of exposure to the test can be established as being equivalent to so many months, or years, of exposure to 'atmospheric corrosion,' whatever that might be" (Ref 2). On the other hand, the economic importance of lifetime prediction, improved understanding of corrosion mechanisms, and the development of advanced material characterization tools have contributed to the continued scientific pursuit of corrosion forecasting methods. A universally acceptable test to predict automotive body corrosion lifetimes has yet to be developed.

During the late 1970s through the early 1990s, the Automotive Corrosion and Prevention Committee of the Society of Automotive Engineers (now SAE International) held a biannual series of well-attended symposia that were dedicated to the understanding and solution of automotive body corrosion issues. By the late 1990s, technological solutions were available and, when properly executed, have provided the long-term corrosion protection desired by the consumers and manufacturers. Since that time, the industrywide effort has given way in large part to scattered individual or small group efforts to reduce cost without sacrificing quality.

This article discusses the commonly encountered forms of automotive body corrosion, corrosion-resistant sheet metals, and paint and sealant systems for corrosion control in automotive body applications. Corrosion problems encountered in automotive exhaust systems and automotive engine coolant systems are described in subsequent articles in this section of the Handbook.

Forms of Corrosion Observed on Automobile Bodies

The complexity of the automotive environment, coupled with unique and sometimes incompatible materials combinations that are necessitated by increasingly dynamic and demanding vehicle functionality requirements, leads to the occurrence of a number of forms of corrosion. While the basic fundamentals of electrochemical corrosion (i.e., liberation of metal ions at the anode and reduction of a species such as dissolved oxygen or the hydronium ion at the cathode) are well established and apply regardless of the particular materials application, corrosion control continues to evolve in response to the specific corrosion environment, economics, and available technology.

The primary types of corrosion observed on automobile bodies are classified as (a) cosmetic or underfilm corrosion, where the combination of compromised paint adherence and the formation of corrosion products leads to increasing amounts of unsightly paint loss, and (b) perforation, where body panels thin to the point of developing holes and losing mechanical functionality. Perforation may be caused by a variety of corrosion types, including general or uniform corrosion, galvanic corrosion, crevice corrosion, pitting, or underdeposit corrosion, and pitting.

General or uniform corrosion occurs over the entire exposed surface of a component and is manifested by a generalized thinning of the material. Because the attack occurs uniformly on the surface of the component, it is the least likely to result in significant mechanical property loss.

Cosmetic or underfilm corrosion is electrochemical in nature and results in paint delamination and exposure of unprotected metal to corrosive attack. Successive exposure to cyclic conditions results in further delamination and exposure of fresh metal. Several phenomenological models to explain cosmetic corrosion have been proposed, but a consensus has not been reached (Ref 3, 4).

Galvanic corrosion results from the contact of two dissimilar metals, both of which must be immersed in the same corrosive electrolyte at the same time. The more active metal or alloy

becomes the anode of the couple and may be subject to accelerated attack. This type of corrosion is becoming a significant concern in the automotive industry since weight-reduction efforts often include the use of aluminum and magnesium, both of which may suffer galvanic attack when in contact with steel components. Careful application of electrical isolation and sealants can disrupt the electrochemical circuit and limit the amount of galvanic attack in such cases. Figure 1 is a schematic illustration of the mechanism of galvanic corrosion.

Crevice corrosion is a severe form of localized attack that is normally associated with small volumes of stagnant electrolyte that can form in occluded areas at joints or under fasteners. Concentration gradients between the stagnant electrolyte and the adjoining exposed electrolyte drive the electrochemical cell. Crevice attack can be very rapid and usually gives little warning because it occurs in generally nonvisible areas. Figure 2 shows a simplified schematic diagram of one model of crevice corrosion.

Poultice or underdeposit corrosion is a special form of crevice corrosion that occurs under deposits of road debris, such as mud that can deposit inside fenders and other partially enclosed areas of vehicles. The poultice can accumulate and concentrate road salts and other potentially corrosive substances. Oxygen concentration gradients under and adjacent to the poultice exacerbate attack under the poultice. Figure 3 shows the mechanism of poultice corrosion.

Pitting is similar to crevice corrosion in that it is a localized attack. It occurs most often in

areas of low pH that are depleted in oxygen, but have high chloride content. Once pitting is initiated, the mechanism is similar to that of crevice corrosion, with the pit acting as the crevice. Pits can initiate at metal inhomogeneities, discontinuities in passive films or other protective coatings, under surface deposits, or at other defects. Figure 4 shows a schematic diagram of the mechanism of pitting corrosion.

All of these forms of corrosion are the result of an interaction of a metal with its environment, and all require the presence of an electrolyte (in most cases water) to facilitate charge transfer. These and other forms of corrosion that occur in the automotive environment are discussed in greater detail in *ASM Handbook*, Volume 13A, 2003.

Corrosion-Resistant Sheet Metals

Beginning in the 1950s, automakers responded to the challenge of increased corrosion of body panels by introducing precoated sheet steels, in particular galvanized (zinc-coated) steels. The term precoated is meant to denote the application of a corrosion-resistant metallic coating to the steel while still in coil form. After fabrication into a part, all metal surfaces (except for cut edges) contain the corrosion-protective sacrificial coating.

In the 1980s, numerous zinc-base sacrificial coatings for steel were developed using existing steel manufacturing infrastructure and popular accelerated corrosion tests of the day. It became apparent that the performance of different coating systems was highly dependent on the nature of the accelerated corrosion test, and correlation with service conditions was poor. Time and experience provided in-service corrosion data that helped lead to the current dominance of electrogalvanized steel (EG or EL), hot dip galvanized steel (GI or HD), and hot dip galvanized steel (GA) for corrosion-resistant automotive body panels. Other more complicated and less robust coating candidates were developed and vigorously marketed, but vanished with increasing understanding of corrosion mechanisms and the development of rational accelerated corrosion test methods. Coating weights are typically 60 to 70 g/m² (0.2 to 0.23 oz/ft²) for EG and GI and 35 to 50 g/m² (0.15 to 0.16 oz/ft²) for GA. The selection of one coating over the other is based

on a balance of economics with the infrastructure of the manufacturing facility, as described below.

Practically all steel automotive skin panels (door outers, floor pans, wheelhouse inners) and structural parts (cross members, rails, beams) thinner than approximately 2 mm (0.08 in.) have a precoat of zinc or zinc alloy for corrosion protection. The incidence of cosmetic corrosion and perforation corrosion of car bodies decreased dramatically during the 1990s to the point where corrosion warranties approaching and even surpassing 10 years are common.

Electrogalvanized steel is recognized as the most robust solution to the manufacturing/functionality needs of corrosion-resistant coated sheet steel for exposed automotive body parts, despite the comparatively higher cost in most markets. The smooth, uniform, and spangle-free surface that results from electroplating zinc onto meticulously cleaned steel strip is very friendly to stamping operations and provides an excellent base for paint. In addition, resistance spot weldability is good. Finally, the relatively low-temperature electroplating process has minimal effect on the mechanical properties of the steel, allowing greater flexibility in the application of increasingly popular high-strength, paint-bake hardenable steel substrates.

Hot dip galvanized steel is produced by passing a freshly cleaned and annealed steel strip through a bath of molten zinc. The corrosion resistance of the resultant zinc layer is comparable to that obtained by electrogalvanizing. The presence of a small amount (0.20 to 0.50 wt%) of aluminum in the hot dip coating can complicate zinc phosphate pretreatment (Ref 6) and subsequent paint adhesion. In addition, hot dip is less robust than electrogalvanized

Fig. 1 Mechanism of galvanic corrosion, which occurs when dissimilar metals are placed in contact with one another and are exposed to a common electrolyte. The more electrochemically active metal will act as the anode and will corrode preferentially (often at an accelerated rate), and the less active metal acts as a cathodic surface for the reduction of an oxidizing species.

(a)

(b)

Fig. 2 Mechanism of crevice corrosion at a joint. Crevice corrosion is common at weldments or sheet metal joints (a) and can occur in apparently sealed lap joints (b).

Fig. 3 Mechanism of poultice corrosion. The most common cause of this type of corrosion is thought to be electrolyte composition gradients. In the example shown, clumps of mud and water have collected, and the varying concentrations of salt and water within the clump encourage corrosion.

Fig. 4 Mechanism of pitting corrosion. As with crevice corrosion, pitting occurs in localized areas that are depleted of oxygen, low in pH, and high in chlorides.

steel to variation in typical resistance spot welding processes, due in part to the effects of aluminum in the hot dip coating and in part to comparatively higher coating weight variability.

Hot dip galvanized steel has a coating that consists of a series of zinc-iron intermetallic compounds. It is produced by heating hot dip galvanized steel to facilitate interdiffusion of the iron and zinc. Galvanized steel has excellent resistance spot welding characteristics and good corrosion resistance. Due to the brittle nature of the zinc-iron intermetallic coating, stamping operations often result in the localized removal of small coating particles, a process called "powdering" (when the particles result from fracture within the intermetallic layer) or "flaking" (when the coating delaminates from the steel surface). Furthermore, impingement by stones or road debris may cause chips that remove paint as well as the metallic coating, resulting in severe localized corrosion.

Paint Systems

Automotive paint systems have two primary functions—to provide a protective barrier against corrosion and to be aesthetically pleasing to the consumer. A typical automotive paint system consists of five layers—pretreatment, electrocoat primer, spray primer, basecoat, and clearcoat. Although the corrosion performance is dependent on the entire paint system, the key components of the paint system for corrosion protection are the pretreatment and the electrocoat primer. The character of the metallic substrate is of utmost importance in the pretreatment and electrocoat primer steps. After electrocoating (a process more correctly termed electrophoretic deposition or cataphoretic deposition), subsequent spray painting steps are minimally affected by the character of the substrate.

The pretreatment for steel and galvanized steel is typically zinc phosphate, while the pretreatment for aluminum is either zinc phosphate or a zirconium polymeric layer, depending on the mix of substrates in the phosphate system. The zinc phosphate pretreatment layer is usually no more than 2 μm thick. It promotes adhesion of the paint layer to the metal substrate. The electrocoat primer is most frequently a cathodically deposited epoxy resin (Ref 7). Electrocoat primer is approximately 20 to 30 μm thick and is the primary layer for paint system adhesion and subsequent corrosion protection. The spray primer layer is approximately 20 to 30 μm thick and is important for stone chip protection and adhesion of the topcoat (basecoat and clearcoat.) The basecoat is typically 15 to 25 μm thick and provides the color of the vehicle. The clearcoat is typically 40 to 50 μm thick and provides gloss and ultraviolet light protection to the paint system. In general, the pretreatment and electrocoat primer thicknesses are consistent among automotive manufacturers, but the spray

primer, basecoat, and clearcoat thicknesses vary depending on the particular chemistry being used by the manufacturer. Some manufacturers use solventborne systems, while others use waterborne systems, powder paint systems, or a combination of the three for the spray primer, basecoat, and clearcoat layers. The use of different paint systems is an attempt by manufacturers to meet increasingly stringent environmental regulations in North America and Europe.

Recent environmental regulations have had a profound effect on the pretreatment and electrocoat primer systems that are now allowable in manufacturing facilities. Postphosphate treatments that contain hexavalent chromium compounds were used for many years to improve the underfilm corrosion performance of painted sheet metal, but hexavalent chromium is no longer allowed in automotive manufacturing facilities in North America and Europe. Similarly, and specifically for environmental reasons, lead has been removed from electrocoat primer formulations. Some tests suggest that the elimination of hexavalent chromium posttreatments and lead in electrocoat primer have had a detrimental effect on the long-term underfilm corrosion performance of vehicles, but continuing advances in other parts of the paint system are closing the performance gap.

Both hexavalent chromium and lead apparently played a beneficial role on metal substrates that had been sanded after the pretreatment process. It is known that sanding (i.e., metal finishing) of the steel, galvanized steel, or aluminum after pretreatment and electrocoat has a detrimental effect on underfilm corrosion performance. Sanding prior to the paint process also can adversely affect corrosion performance, particularly on aluminum. Therefore, care must be taken to minimize defects in the substrate and the paint coating that require sanding.

Surface Preparation for Paint Processes

Metal Cleaning. Preparing the surface for painting begins with cleaning oil and grease from the surface and removing solid contaminants such as fibers and weld balls (spatter). The cleaning system consists of alkaline cleaners and water neutralizers/rinses. If solid contaminants are not removed from the metal surface, a variety of defects that may necessitate sanding or other dirt-producing rework of the paint system may result. If oils and grease are not removed, they can inhibit the nucleation and growth of phosphate crystals on the metal surface and provide sites for adhesion loss and subsequent corrosion.

The phosphate portion of the pretreatment process consists of a rinse conditioner, phosphate stage, rinses, and posttreatment. The rinse conditioner provides sites where phosphate crystals can nucleate on the metal surface. In the phosphate stage, zinc phosphate crystals deposit at

the nucleation sites. Excess process chemicals are removed, and the remaining chemicals are neutralized in the rinse stages. The posttreatment typically is a zirconium polymeric or similar rinse that prohibits further crystal nucleation and seals any surface that is not covered by phosphate crystals. The final rinse prior to the electrocoat primer process is critical, as unreacted pretreatment chemicals can adversely affect the success of the electrocoat primer bath.

Critical characteristics of the pretreatment system are phosphate crystal size and phosphate coating weights. It should be noted that aluminum parts are frequently processed concurrently with steel and galvanized steel parts, often as a closure panel on a mixed-metal vehicle. The inclusion of aluminum substrates in the pretreatment process presents some challenges to the system. In particular, the outermost aluminum oxide layer is etched in the phosphate stage and significantly increases the amount of sludge produced in the bath. If the liberated soluble aluminum ions are not removed from the bath as sludge, they will inhibit deposition of phosphate on the metal. Similar concerns are valid for magnesium body panels. For aluminum-intensive vehicles, dedicated pretreatment processes that do not have to satisfy the needs of mixed-metal vehicles may be used.

The electrocoat primer process immediately follows the pretreatment process. Almost all automotive manufacturers now use electrodeposition to apply the primary corrosion protection layer to the vehicle body. In the cathodic electrodeposition process, the vehicle is negatively charged and immersed into a tank containing positively charged electrocoat primer. The electrocoat primer is attracted to the metal and deposits uniformly on the pretreated metallic surfaces. Both exterior and interior surfaces are coated, although the coating on interior surfaces may be thinner than that on exterior surfaces due to throwing power limitations. The thickness of the electrocoat primer can be varied by changing the voltage and by operating auxiliary anodes in shielded areas.

After the vehicle is coated with electrocoat primer, the body is rinsed to remove excess solids that could result in surface defects. The excess solids are recovered and returned to the electrocoating tank. Vehicle bodies typically are baked in an oven for 30 to 45 min to cure the electrocoat primer for optimum performance. It is important for all parts of the vehicle to attain an adequate level of cure, which can be challenging considering the varying thicknesses of the steel and the numerous enclosed sections on the vehicle. Inadequate cure significantly reduces the corrosion protection on the vehicle. Overcure can reduce the adhesion of the spray primer to the electrocoat primer and can cause components in the coating to bake out, both of which are detrimental to long-term corrosion performance.

Spray primer or primer-surfacer provides several functions to the paint system, the most

important being protection from stone chipping. Stone chips that penetrate through the spray primer to the electrocoat or to the metal surface provide sites for corrosion initiation. The goal of the spray primer layer is to dissipate energy from impinging stones, thus minimizing damage to the underlying corrosion preventive layers. Other important functions of the spray primer layer are to provide adhesion between the topcoat (basecoat and clearcoat) and the electrocoat primer and to keep ultraviolet (UV) light from reaching the UV-sensitive electrocoat primer layer.

There are several different spray primer paint systems being used by automotive manufacturers, depending on the company strategy for meeting environmental regulations. Solventborne, waterborne, and powder spray primers are electrostatically sprayed onto the vehicle. The vehicle is grounded, while the paint is positively charged. This process provides the most efficient transfer of paint to the vehicle body. Only the exterior surface, door openings, and underhood areas are sprayed with spray primer.

After application of the spray primer, the paint is cured for a prescribed time/temperature cycle in an oven. Cure of the paint is extremely important for the performance of the coating. Undercure (too little time or too low temperature) prevents the primer from adequately protecting the underlying layers from UV light and stone chips. Overcure (too much time or too high temperature) causes the paint to become brittle, resulting in degraded chipping performance.

The topcoat consists of basecoat and clearcoat that are applied wet-on-wet, or without a full bake between layers. The primary purposes of these two layers are to provide aesthetics (color, gloss) and UV protection. Basecoat layers are typically solventborne or waterborne. Clearcoat layers are usually solventborne, although there has been progress in the application of powder clearcoat technologies.

Automotive topcoat is applied electrostatically, in the same manner as the primer layer. The applied thickness of each layer is critical—in basecoat to attain the desired color and in clearcoat for protection from UV light. Curing of this layer is also important to attain the appropriate performance characteristics. A 30 to 40 min bake is typical for topcoat systems.

Coil Coating

Some automotive manufacturers use coil-coated or preprimed steel as a means to improve corrosion protection at areas where it is difficult to apply electrocoat primer. This process provides a primer layer with an extremely consistent thickness. In the coil-coating process, a coil of steel typically is pretreated with zinc phosphate and is continuously coated with a polymeric film, which is cured before the coil is rewound for shipment to the user. The coil-coated material is then subjected to the usual stamping and welding processes that comprise automotive body construction.

The coil-coated parts are then processed through the spray primer, topcoat, and clearcoat processes by the normal methods outlined previously. Note that the coil-coated parts are subjected to the same cleaning and pretreatment processes as noncoil-coated parts, but no phosphate crystals deposit onto the primed surface.

Automotive Exhaust System Corrosion

Joseph Douthett, AK Steel Corporation

CORROSION ENGINEERS looking for the optimal real-world environment to evaluate stainless and coated steel alloys need to look no further than the modern automobile and truck exhaust system. Imagine a test sequence that includes an aqueous environment with a pH that varies from basic 8 to 9 down to acidic 2, with dissolved chloride levels from 50 to 2000 ppm. Now, include cyclic humidity conditions where components experience temperatures from ambient up to 870 °C (1600 °F). Finally, add crevices and welds, mix the various materials, shake with a combination of low- and high-cycle fatigue stresses, and one has the modern automotive exhaust system. Steel automotive exhaust systems suffer from at least eight common forms of corrosion, including general cosmetic attack, chloride pitting, crevice, galvanic and intergranular corrosion, hot salt attack, oxidation, and corrosion fatigue. The general cosmetic attack is basically a form of superficial pitting discoloration, as opposed to the more traditional carbon steel general attack where base metal is removed in measurably thick layers.

Since the early 1970s, automobile exhaust systems have gone through a gradual but steady evolution of design and materials. From the days of aluminized carbon steel mufflers, often with bare carbon steel connecting and internal tubes, today's (2006) exhaust system is a high-technology sound-deadening, pollution-removing system with one or more catalytic converters, mufflers, resonators, and flexible joints, all constructed of stainless steel. With an average North American annual production of 16 million light trucks and cars, the exhaust industry yearly consumes large volumes of stainless alloys, including many miles of fabricated tubing. There are close to 200 million vehicles on North American roads, which means that a new production vehicle can expect to avoid recycling and the crusher for some 13 years after first being sold. With initial car loans close to 60 months, it is understandable why car builders are pushing the original equipment producers to develop systems with 7 to 10 year durability and warranties of 3 to 4 years.

Traditionally, the normal exhaust system has been divided into two parts: a hot end and a cold end (Fig. 1). The hot end, closest to the engine, includes the exhaust manifold, downpipe,

catalytic converter, and often a flexible coupling. On some vehicles, the main underbody catalytic converter is supplemented by a smaller close-coupled (next to the manifold outlet) light-off converter designed to reduce pollution on vehicle start-up. The exhaust hot end is considered a part of the vehicle emission control system and therefore comes under government-mandated warranties, which, in 2004, became 10 years and 193,000 km (120,000 miles). The cold end of the exhaust includes the resonator, intermediate pipe, muffler, and tail pipe. Its durability target or warranty is chosen by the carmaker based on competitive pressures and consumer complaints. Today (2006), cold end exhaust targets are to have the original equipment manufacturers (OEM) systems survive on the vehicle a minimum of 7 to 10 years. Cold end warranties are generally 3 to 4 years and 58,000 to 77,000 km (36,000 to 48,000 miles).

Figure 1 is a schematic of the standard OEM exhaust system and lists the stainless alloys most often used to construct these components. For

each component in Fig. 1, an attempt was made to add a typical in-service maximum metal skin temperature. Obviously, that temperature varies with engine, driving cycle, component design, and degree of insulation and heat shielding. Table 1 shows the compositions of the most common alloys used in exhaust system construction. The heavy use of ferritic 400-series stainless alloys is immediately obvious. The 300-series stainless steels in North America have limited use, most often as tail pipes or fabricated manifolds. Carbon steels, normally as aluminized (type 1) steel, find their way into some heat shield applications, as occasionally do aluminum alloys. Bare carbon steels still are used as 9.53 to 12.7 mm (0.375 to 0.500 in.) thick flat flanges or as 12.7 mm (0.5 in.) diameter rod hangers to attach systems to the car frames. In normal exhaust construction, stainless components will range in thickness from 0.5 mm (0.020 in.) muffler wraps up to 2 mm (0.080 in.) wall thickness downpipes. Some fabricated stainless steel flanges will measure 3.1 to 4.7 mm (0.125

Fig. 1 Exhaust system components with typical upper metal skin temperatures and alloys of construction. P/M 409L and P/M 434L produced by powder metallurgy (P/M) processing

to 0.187 in.) thick, with flat flanges up to 9.5 mm (0.375 in.). This is the thickest stainless coil plate that is made in North America. Currently, approximately 60% of North American exhaust system components are constructed from bare 11% Cr T409, with another 20% upgraded to hot dip aluminum-coated T409 (referred to here as AL409). The 17 to 18% Cr stabilized ferritics (T439, 18Cr-Nb, 441, and 436L) and the austenitic alloys 304L and 309S make up most of the remaining tonnage, except for an 11 to 12% Cr ferritic alloy, 409Ni, used in some heavier flange stampings. A Japanese-developed hot end high-chromium alloy referred to as 430M has seen limited use, mostly on vehicles brought to the United States from Japan.

High-Temperature Corrosion

Oxidation. With exhaust metal skin temperatures of 870 °C (1600 °F) or higher, catastrophic oxidation is a concern with exhaust components. Experience coupled with laboratory cyclic oxidation testing has generally helped avoid such failures. Tables 2 and 3 show the results of cyclic oxidation (25 min of heat followed by 5 min of ambient air cooling) exposure at 815 °C (1500 °F) and 900 °C (1650 °F) in a natural-gas-fired atmosphere on several of the more standard exhaust hot end materials. The

316Ti alloy is a flexible coupling alloy, while AL439 is an aluminum-coated 439 long-life material, developed for some luxury car muffler applications. Weight changes were recorded during and after 260 to 350 h of testing at temperature. The ferritic stainless alloys showed weight increases as oxide scales thickened over time. The austenitic alloys (304L, 316Ti, and 309S), however, tended to show weight decreases. This was due to the higher coefficients of thermal expansion, which caused protective scales to spall over time, leading to weight loss and sample thinning. While stronger and more formable, the thinning and loss of scale characteristic of austenitic stainless alloys in cyclic heating has proven to be the "Achilles heel" of this class of exhaust materials in hot end exhaust applications.

In cyclic tests at 900 °C (1650 °F), 409 alloy had a thick scale characteristic of breakaway catastrophic oxidation. The 17% Cr titanium-stabilized 439LT coupon showed the beginning of excessive scaling. These laboratory-tested coupons are shown in Fig. 2. The 18Cr-Nb, (designated 18CR-CB in Fig. 2), AL409, and AL439 samples had stable scales, although the AL409 developed heavy oxidation at sheared edges and at the punched hole not protected by a coating of aluminum. Of the austenitic alloys, 309S was the best, although scale losses were high. The 304L and 316Ti alloys lost so

much weight that they structurally fell apart. Aluminum-coated stainless alloys benefited at elevated temperatures (> 540 °C, or 1000 °F) by having the aluminum coating diffuse into the base alloy to form a scale-resistant iron-aluminum intermetallic layer that then formed a thin scale of Al₂O₃ on the sample surface.

From an oxidation standpoint, Table 4 shows what is considered to be a conservative upper temperature limit for standard exhaust alloys in cyclic oxidation service. This temperature is generally not exceeded in continuous service. However, brief exposures to temperatures 28 to 55 °C (50 to 100 °F) above the cyclic service limit can be tolerated with little likelihood of seeing the onset of catastrophic oxidation.

Hot Salt Attack. When salt crystals are added to the high-temperature oxidizing environment, the phenomenon known as hot salt attack can occur. This form of attack is more rapid and catastrophic than aqueous chloride pitting on a scaled stainless surface. Hot salt attack occurs when a quantity of salt is trapped against a hot surface. In normal converter/downpipe applications, salt-laden water splashes against the hot exhaust components, the water evaporates, and salt crystals can accumulate on the steel surface, leading to hot salt attack. Crevices, insulation, or depressions in the formed steel surfaces provide collecting basins for salt solutions to be trapped.

Water will evaporate, leaving behind salt deposits. With high-enough temperatures, such deposits can melt and act as a fluxing agent capable of removing the stainless alloy protective chromium oxide scale. This fluxing reaction occurs according to the equation:

The sodium chromate is water soluble and easily removed. With the protective scale gone, the salt and free chloride then react with chromium in the base steel according to the following

equations:

The chromium chloride is volatile, and the sodium chromate is water soluble. The result is intergranular attack.

An example of hot salt attack is shown in Fig. 3. Two layers of 0.203 mm (0.008 in.) thick T304 were sandwiched together with an internal layer of fiber insulation to form a catalytic converter heat shield. The semicircular ends of the laminate heat shield were not watertight. Salt-water soaked the fiber mat, putting salt crystals in intimate contact with the 304 surfaces. The 304 layer closest to the hot converter shell experienced temperatures high enough to melt the salt. The subsequent intergranular attack is shown in the metallographic cross section (Fig. 3). Hot salt attack is a more rapid form of corrosion than chloride pitting. The accompanying intergranular corrosion occurs over a wide area, often removing layers of metal, much like catastrophic oxidation.

Laboratory screening tests to evaluate the hot salt corrosion resistance of exhaust alloys is fairly simple. Coupons are immersed in a concentrated sodium chloride (NaCl) salt solution for 5 min, placed in a metal rack, and heated in air for 2 h. At the end of the heating cycle, the samples are cooled for 5 min and again immersed in salt solution. Ten salt exposures followed by heat are carried out at each temperature. Samples are weighed before and after testing, and weight loss per unit of sample surface area is calculated. A battery of hot salt tests generally consists of 10-cycle evaluations at each of five different exhaust temperatures from 400 to 800 °C (750 to 1470 °F). This temperature range covers hot salt environments from the

intermediate pipe to the manifold. Weight loss versus temperature plots are shown in Fig. 4 and 5. Figure 4 compares the resistance of five bare exhaust alloys, while Fig. 5 shows results for standard exhaust alloys 409 and 439 and compares them to hot dip aluminum-coated carbon steel (ALT1) and coated 409 and 439. Figure 5 also includes the aluminum-bearing (1.7%) stainless heat-resistant alloy AK 18SR, which contains 18% Cr.

The hot salt tests on standard uncoated stainless exhaust alloys in Fig. 4 show that weight losses increase with test temperature. The high corrosion rates at 800 °C (1470 °F) make sense, given that 800 °C (1470 °F) is near the melting point of pure NaCl. Increasing the chromium content proved beneficial, as did raising the molybdenum content. Alloy T304 with 18%Cr-8%Ni had approximately the same hot salt resistance as the 17 to 18% Cr ferritic alloys (439, 18Cr-Nb, and 436L).

Figure 5 shows how adding aluminum, either as a coating or alloy addition, affected hot salt resistance. Adding aluminum to the base alloy was beneficial, but there was not as much improvement as when it is added as a coating. Even carbon steel after aluminizing resisted hot salt attack better than the bare stainless alloys. At most of the higher temperatures used in the hot salt evaluations, the aluminum coating alloyed with the substrate, forming an iron-aluminum intermetallic with an outer scale of Al_2O_3 .

Thermal Fatigue. A final form of environment-assisted hot end exhaust system failure is thermal fatigue. This type of component failure is oxidation-assisted mechanical fatigue and generally occurs only in hot end applications. Figure 6 shows the exterior of a truck T409 stainless steel catalytic converter shell that failed in service, developing a through-thickness fracture at the deepest midlength rib on the washboardlike converter outer surface. Also in Fig. 6 is a 50× cross section of the rib with a

series of shallow notches in the metal, characteristic of fatigue. Cyclic stresses on the hot shell surface lead to small surface cracks that, due to the elevated service temperature, are oxidized. The oxide within the shallow cracks wedged open the steel surface so that, on subsequent heating cycles, a notch was formed that cracked further and again oxidized. With time, one of these fissures oxidized more rapidly, and eventually, so much of the steel cross section was cracked and weakened that the next heatup led to a ductile rupture failure of the shell. The rib that fractured in this component happened to be the deepest stamping in the converter shell and was situated in a location that was exposed to high heat from internal exhaust gases. Had the rib been shallower or possibly insulated from the internal gases, the temperature and stress concentrations would have been less and fatigue would have been avoided. Without changing shell design, the way to eliminate the problem is to move to a stronger, more oxidation-resistant alloy or thicken the shell wall.

Thermal fatigue is obviously design-critical. Designs that concentrate in-service stresses or lead to hot spots promote such failures. Experience has shown that failed or too few hanger assemblies are a major cause of thermal fatigue. Heat-affected zones (HAZs) are sensitive to such vibrational failures, particularly a ferritic 400-series alloy HAZ if the metal on the other side of the weld is a stronger, higher coefficient of thermal expansion 300-series austenitic stainless steel. As with the converter shell described previously, sometimes a design showing fatigue

Fig. 6 Catalytic converter shell with thermal fatigue cracks in formed exterior surface rib. In cross section at bottom, note numerous outer-diameter surface cracks. 50×

problems must remain, and material change must be considered. In these instances, an alloy with greater strength at temperature or more oxidation resistance is the best solution. Table 5 is a comparison of exhaust alloy strength at 815 °C (1500 °F). The 300-series alloys offer the better strength but not necessarily the better resistance to oxidation. Among the 400-series alloys, the addition of niobium, Nb (or columbium, Cb) improves elevated-temperature strength. Alloys such as T441 or 18Cr-Nb have frequently found favor as a way to upgrade the elevated-temperature strength and oxidation resistance of T409.

Cold End Exhaust Corrosion

Exhaust components further from the engine experience lower gas temperatures and conditions where condensate forms in exhaust service. Added to these condensates are the exhaust gas ions and compounds formed from combustion of fuel. These include carbon dioxide (CO₂), sulfur trioxide (SO₃), ammonia (NH₃), and water (H₂O). They leave the catalytic converter and form droplets of condensate when dewpoints of 120 to 175 °C (250 to 350 °F) are encountered on cooler intermediate pipe and muffler walls. Add to this mix gaseous hydrogen chloride (HCl) from chlorides left on converter ceramic monoliths (when precious metals were deposited from a chloride-rich solution), and the potential exists for chloride pitting in an acid environment. New converters can produce condensates with 1000 to 2000 ppm of chlorides from the water-soluble chlorides left on ceramic honeycomb biscuits after manufacturing. These chlorides (as gaseous HCl) are absorbed in water vapor from the combusted hydrocarbons. In several hundred miles of driving, the chloride level of new car condensates will drop below 100 ppm and approach the 50 ppm of chloride in normal gasoline. As the chloride level returns to 50 ppm, the pitting tendency decreases, but still the potential exists for pitting, particularly with dried chloride deposits that are rewetted with each new driving cycle.

Condensate Pitting Corrosion. As the dewpoint on cool component walls is reached, droplets of condensate laden with chlorides, sulfur compounds, and ammonia ions form. The amount of diluting water present is dependent on

heat-up rate and climatic conditions. Initially, the condensate can be neutral or basic (pH ≥ 7), depending on the amount of dissolved ammonia. As the ammonia boils off and the droplets shrink in size, the pH tends to become more acidic. Some pH values have been measured as low as 1 to 2. The slower the rate of evaporation, the longer the time that chloride-laden acidic droplets have to initiate and propagate pits. For the same mileage, short driving trips where mufflers never get hot enough to completely dry out are more detrimental to muffler longevity than extended interstate trips.

Drain holes in muffler end plates are important as a means to flush out condensates and accumulating salt deposits. A double-walled T409 muffler, shown in Fig. 7, was constructed with no drain hole and was removed after 4000 km (2500 miles) of driving. Internal condensate puddled in an area adjacent to a spot-welded internal baffle and pitted through both the inner and outer shell. Numerous small through-thickness pits created by the trapped condensate formed on the inner shell. A drain hole put in the bottom of the single-thickness muffler end plate and mounted on the vehicle with an angle to ensure drainage would have prevented such rapid pitting. On some vehicles, a drain hole is replaced by a siphon tube designed to use venturi-like air flow to evacuate condensate. Such devices only function if the vehicle is in motion and must be mounted with care for proper operation.

Laboratory tests to evaluate condensate resistance of stainless exhaust alloys consist of a three-step procedure. Coupons 75 by 100 mm (3 by 4 in.) are heated in air for 1 h at 260 °C (500 °F) to simulate heat conditions inside the muffler. At this temperature, a light straw-colored heat tint develops and slightly deteriorates surface corrosion resistance. After the heat cycle, the samples are placed in a beaker partially filled with synthetic condensate solution (Fig. 8a). This aqueous solution contains 5000 ppm of sulfate ion (SO₄²⁻), 100 ppm of chloride ion (Cl⁻), 100 ppm of nitrate ion (NO₃⁻), 100 ppm of formic acid (HCOOH), and initially has a pH of 5.3 to 5.5. The solution is boiled 16 h, with no liquid being added and no condenser on top of the beaker to maintain the volume. As the solution evaporates, the pH decreases to 3.3 to 3.5 by the conclusion of the test cycle. The evaporating condensate creates a

Table 5 Comparison of elevated-temperature strengths for commonly used exhaust stainless steel alloys

Alloy	Short-time 0.2% yield strength		Short-time ultimate tensile strength		Rupture strength(a)		Fatigue endurance(b)	
	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi

Fig. 7 South American muffler (409 shell and baffles) designed without drain holes in end caps or baffles (4000 km, or 2500 miles, of driving). Lack of condensate drainage has led to premature pitting perforations.

Fig. 8 Laboratory test to evaluate condensate pitting corrosion. (a) Arrangement of sample. (b) Pitting condensate corrosion results for six exhaust alloys. Pit depths represent the average of the ten deepest pits. Details of the test procedure are given in text.

pitting condition similar to that which occurs in a muffler. After boildown, the coupons are exposed for 6 h in a humidity cabinet at 50 °C (125 °F) and 85% relative humidity. The humidity cabinet rewets dried salts and allows pitting to continue. One test cycle consists of the daily three-part routine. Total test duration is generally 8 to 10 weeks (40 to 50 daily cycles), with weekends spent in the humidity cabinet. Samples are periodically removed from the test for pit depth measurements.

Pit depths were measured by one of two methods. After a light glass bead blasting or peening to remove built-up corrosion deposits, pointed micrometers were used to measure the deeper-appearing pits, and an average of the ten deepest pits was calculated. The second method involved chemically cleaning corrosion debris with a solution of inhibited 1 to 1 HCl/H₂O in accordance with ASTM G 1 (Ref 1). The ten deepest pits were then circled, and a calibrated microscopic eyepiece was focused on the bottom of the pit and then the surface to estimate the pit depths. Agreement between the two depth-measuring procedures was fairly good.

Figure 8(b) shows the boiling beaker condensate corrosion results for six exhaust stainless alloys, four bare and two aluminum coated. On this graph, 500 μm represents approximately 0.508 mm (0.020 in.) of pit depth. Bare 409 (11% Cr) suffered the deepest pitting attack, followed by 17%Cr 439, 18%Cr-8%Ni T304, and 17%Cr-1%Mo 436L. The aluminum-coated 409 outperformed all the bare stainless alloys, while aluminized 439 was not exposed long enough to show any appreciable pits. The aluminized 409 showed no pitting for 28 of the 40 test cycles, the time for the acid chloride solution to corrode away the galvanic protection offered by the aluminum outer layer and the underlying iron-aluminum intermetallic diffusion coating. Unlike coated carbon steel, stainless alloys with hot dip aluminum coatings have a diffusion layer of iron-aluminum under the thicker aluminum coating that also offers galvanic sacrificial protection for the stainless substrate.

Exterior Salt Pitting. On cold end exhaust components, where skin temperatures do not quickly boil away aqueous solutions, exterior stainless surfaces undergo wet chloride pitting. This classic form of pitting corrosion occurs because cold end exhaust components experience more wet time due to their location under the vehicle, and the lower skin temperatures extend drying times. Unlike internal condensate pitting (discussed earlier), exterior salt corrosion does not involve acidic pH levels. Exterior surfaces experience a variety of chloride compounds. Sodium chloride (rock salt), the mainstay of road deicing compounds for the last 50 years, has recently been joined by calcium and magnesium chloride in either solid or liquid form as a pre-treatment prior to snowfall or when low temperatures are anticipated. For traction control, many states use sand or fine aggregate (crushed rock) mixed with the salt. Poulticelike mixtures of mud and chlorides coated on exhaust

component surfaces promote pitting and form crevice-corrosion conditions.

The more recent use of calcium chloride, not only as a winter antiicing compound but as a sprayed-on summer road dust deterrent, could be introducing a second pitting problem for exhaust components as well as automotive exterior trim. Calcium chloride (CaCl_2) crystals are hygroscopic. When deposited on metallic surfaces, such crystals absorb water vapor, become more adherent, and, with the presence of chlorides, continue the pitting process.

Exhaust gas temperatures lead to exterior heat tinting of cold end components and outright oxidation and scale formation on hot end components. Heat tints on intermediate pipes, mufflers, and tail pipes are generally thin interference oxide films that vary in color from straw yellow at low temperatures (200 to 260 °C, or 400 to 500 °F) to darkening shades of brown and even blue as temperatures increase toward 540 °C (1000 °F). Above approximately 650 °C (1200 °F), the scales thicken and take on the dark-brown or gray coloration generally associated with oxidation. Experience has shown that the presence of scale and heat tint lead to increased pitting attack. On cold end components, this increase normally takes the form of many shallow pits rather than a few deep pits. The red iron oxide formed within and around the rim of these shallow pits gives the tinted surface the appearance of having undergone significant corrosion, albeit cosmetic or superficial in nature. The greater the degree of heat tinting, the more rapid and severe the resultant cosmetic attack. The increased propensity to pit on a tinted surface may be related to the rougher surface being a collection for chlorides. Another theory suggests that the increased chromium level in the oxide film causes a corresponding lower chromium level in the substrate immediately under the heat tint layer. Wet chlorides penetrating cracks or voids in the heat tint find an active, lower-chromium-content alloy underneath.

Figure 9 shows a single-shell 17%Cr T439 muffler with 106,500 km (66,000 miles) of exposure during driving. Note the band of cosmetic rust running circumferentially around the mid-length of the muffler. Sitting between two rows of spot welds, this area is probably an internal tuning chamber that ran hotter and caused the external surface to tint and cosmetically corrode in the presence of road salt and moisture. Heat

Fig. 9 T439 muffler shell after 106,500 km (66,000 miles) of driving. Cosmetic superficial pitting seen in band above a tuning chamber area that saw higher temperatures and heat tinting

tint and exterior salt cosmetic attack were the main reasons behind the development of hot dip aluminized 409 muffler steels. Being anodic to the steel substrate, the aluminum coating prevents surface red rust from forming on 409 until the exterior aluminum coating and alloy layer of iron-aluminum intermetallic underneath are consumed. Aluminum corrosion product is white and not nearly as visible from a distance. Aluminum or the Al-10wt%Si alloy used on these coated stainless alloys will not heat tint, retaining a silver metallic appearance until it is consumed in the iron-aluminum intermetallic layer and as Al_2O_3 . After the aluminum is consumed, which generally requires temperatures above 427 °C (800 °F), the coated T409 becomes dark gray in surface appearance and is prone to red rusting. To further illustrate the cosmetic corrosion benefits of aluminum coatings, Fig. 10 shows two exhaust systems from the same-make vehicle. One is completely constructed of aluminized 409, except for flanges and hangers. The all-AL409 unit saw 201,600 km (125,000 miles) of driving. The second system has bare 409 for the exposed pipes and saw only 56,500 km (35,000 miles) of service. While both systems are of sound integrity, the cosmetic attack of the bare 409 pipes is obvious. North American cold end exhaust components, at least muffler wraps and tail pipes, visible to the public have seen significant growth in the use of aluminum-coated 409 stainless, depending on the 11% Cr base alloy for durability and the thin exterior aluminum surface (coating weights generally are applied at a minimum of 85 g/m², or 0.25 oz/ft², total for both sides) for cosmetic corrosion resistance. The protective nature of the aluminum coating, galvanic even to uncoated adjacent filler welds, has been found to be a more effective way to avoid cosmetic rust than sprayed-on black paints applied after component manufacturing. Such paints are often seen to peel and flake in a year or less and can actually make corrosion worse due to their tendency to trap moisture and salt against the underlying steel surfaces.

To be realistic, laboratory external salt pitting tests need to combine simulated road salt splash with cyclic heating and exposure to high but

Fig. 10 Two identical exhaust systems collected from the field. The upper system is AL409 with 201,600 km (125,000 miles) of service. The lower system has bare T409 tubes with 56,500 km (35,000 miles) of service.

noncondensing humidity. The samples should be wet but not washed. Coupons can be flat, rectangular panels or have 90° bends and even 25 mm (1 in.) diameter stretch domes pushed to a height of 5 mm (0.2 in.) added to better evaluate the effect of forming, particularly on coated alloys. Road deicing salts are often mixtures of chlorides, but most laboratory tests use only NaCl. As described previously, sets of test coupons were removed on a periodic basis, cleaned, and average pit depths measured. Heat, salt, and humidity can be combined into endless test possibilities, with the heat-cycle temperature chosen based on which exhaust component skin temperature (Fig. 1) is being simulated.

External pitting test A (muffler shell temperatures) was carried out in a controlled relative humidity (RH) cabinet. Coupons received a weekly 260 °C (500 °F) 1 h heat exposure to form a heat tint. The samples were then placed in the cabinet and given a repeating 6 h cycle of:

- 15 min immersion in 5% NaCl solution
- 20 min dry in 40 °C (104 °F)/35% RH air
- Raise conditions to 60 °C (140 °F)/85% RH and hold balance of cycle

Figure 11 shows average pit depths after 1176 h of testing with the procedure outlined previously. Results show the benefit of increasing chromium content and, at longer test times, of increasing the molybdenum (1.3% in 436M2) content. The aluminum coating was also beneficial until the galvanic protection of the free-aluminum and alloy layer was eliminated. Then, the underlying 409 base alloy corroded at a rate approaching that of the bare base alloy.

Test A requires a sophisticated programmable humidity cabinet to conduct. A second, simpler test, external salt pitting test B, was developed and has been proven to correlate well with field survey results as well as on-car component durability tests. Test B uses a weekly heat treat cycle of 1 h, but only a once-per-day salt dip and air dry, and spends the balance of each day at 85% RH and 60 °C (140 °F). Figures 12 through 14 show the results of conducting test B at varying

Fig. 11 Comparison of average pit depths over time for four exhaust stainless steel alloys exposed to cyclic exterior salt humidity cabinet pitting test A. See text for test details.

heat treat temperatures, namely 315, 425, and 540 °C (600, 800, and 1000 °F), respectively. The 315 °C (600 °F) test results resemble test A at 260 °C (500 °F). At these hotter muffler temperatures, 17%Cr T439 and aluminum-coated 439 (a premium durability product used on some luxury vehicles) show essentially no attack after 12 weeks of testing. At 425 °C (800 °F) intermediate pipe temperatures, the depth of pitting increased on all the alloys evaluated. Finally, with a converter can 540 °C (1000 °F) heat cycle, bare 409 began rapid pitting, which appears to cease between 2 to 4 weeks, only to reinitiate after 4 weeks. Visual coupon observations indicated the 540 °C (1000 °F) temperatures caused 409 to form a thicker scale jacket than on the higher-chromium alloys. This thicker oxide film filled active pits with debris that shut down the pitting mechanism for a time. The

Fig. 13 Exterior cyclic salt pitting test B after 12 weeks with a weekly 1 h 425 °C (800 °F) heat exposure and daily salt solution dip and humidity exposure

Fig. 14 Exterior cyclic salt pitting test B after 12 weeks with a weekly 1 h 540 °C (1000 °F) heat exposure and daily salt solution dip and humidity exposure

decrease in pitting corrosion of AL409 at this highest temperature was associated with the total alloying of the free-aluminum layer. While no longer bright cosmetically, the thick alloy layer does provide galvanic and barrier coating resistance to chloride attack. Results shown here with a 540 °C (1000 °F) heat treatment do appear to correlate with converter exhaust systems in the field. One week in this test B cycle appears equivalent to 1 year of service in the severe salt belt of North America.

Crevice corrosion occurs when liquids can penetrate enclosed areas with a limited supply of oxygen and set up a concentration cell. With stagnant solutions that have limited supplies of oxygen, the stainless alloys cannot maintain their passive protective films. The presence of chlor-

ides only accelerates the reaction. Figure 15 is a schematic of such a crevice. In cold exhaust applications, there are three areas particularly prone to crevice attack. One is between the wrap and shell of double-walled mufflers, and the other is on external muffler surfaces when belly bands are used for underbody attachment. Welded-on rod or sheet-metal hangers can also cause small crevices where they attach to the muffler end caps or exhaust tubes. A third area of potential crevice attack is the muffler internal surface where baffles are spot welded. Small gaps between the baffle bottom surface and inner muffler shell can create a crevice where stagnant liquid can collect. To combat baffle crevice corrosion, the baffles frequently have a drain hole on their bottom edges to permit liquids to pass through on their way to drain holes in the end plates.

Crevice attack between the wrap and shell of mufflers is primarily the result of leakage from internal condensate and intrusion of external road salt solution through the muffler shell lock seams and rolled-on end plates. Figure 16 shows half of a T409 double-walled conventional muffler with the wrap (right side) and shell (left side, with baffles and internal tubes attached) separated. The component experienced 132,500 km (82,000 miles) of driving service. In this figure, the two single-wall end plates have been removed by sawing. The insert in Fig. 16 shows an end view of the muffler and the lock seam used to attach the wrap to the shell. There is another lock seam on the other side of the

Fig. 15 Schematic of crevice-corrosion condition where stagnant liquid with a limited supply of oxygen leads to breakdown of the stainless alloy passive film

Fig. 16 Dual-wall 409 muffler after 132,500 km (82,000 miles) with crevice corrosion between the outer wrap and inner shell

muffler, and this one joins the inner shell oval. Springback of the 180° lock seam bends prevents an airtight seal and allows acid condensate from inside the muffler and road salt solution from outside the muffler to enter the narrow space between the shell and wrap. This interwrap area has no drainage, and salt levels can build up, with resultant corrosion on the inside of the outer wrap and outside of the inner shell. Because muffler exterior wraps are often the thinner of the two layers, perforation generally occurs first to this layer. In Fig. 16, the pinholes of perforation appear in greater number on the thinner 409 wrap. Single-shell mufflers do not have such crevices and offer longer corrosion durability, often at the expense of increased noise-level concerns.

To combat double-shell interwrap crevice corrosion, muffler builders have begun adopting a double-lock design where the wrap and shell are simultaneously roll locked together on the same side of the muffler. Figure 17 shows a cross section of this form of muffler seal. While this forming technique requires more power, it does retard liquid intrusion into interwrap areas.

Fig. 17 Muffler lock seam constructions. The double-lock seam construction (right) helps prevent liquid penetration between the wraps.

Fig. 18 Muffler end cap constructions. The more desirable corrosion-resistant muffler design is shown at bottom.

Another source of interwrap leakage in double-wall mufflers is rolled-on end caps. As shown in Fig. 18, if the outer wrap is tucked into the head and not bent 180° with the end cap and inner shell, salt solution intrusion from outside surfaces is possible. The wrap needs to be extended into the shell/end cap seam and the entire thickness rerolled to seal off leaks. Figure 19 shows an AL409 muffler wrap after 27,400 km (17,000 miles) of driving, with internal leakage around the rolled head causing exterior corrosion of the protective aluminum coating. The aluminum-coated stainless alloys, when used in double-wall muffler construction, have been found to improve leak tightness. The softer free-aluminum exterior coating acts similar to a gasket in crimping operations when compared to the smoother, harder mating surfaces presented when bare stainless shells are joined.

Exterior wrapped belly bands for muffler attachment to the car frame also create life-shortening crevices. Figure 20 shows a muffler shell constructed of T409 after 114,500 km (71,000 miles) of driving in Montreal, Canada. The belly band has been removed and the entire surface glass bead blasted to expose corrosion

Fig. 19 Muffler with 27,400 km (17,000 miles) of service and AL409 wrap and end cap. Condensate leakage through the rolled head has attacked the aluminum coating.

Fig. 20 Crevice corrosion of a 409 muffler shell under a belly band (removed from photo) on a vehicle driven 114,500 km (71,000 miles) in Montreal, Canada.

damage. The crevice under the band has perforated the 409 shell, structurally damaging the shell integrity.

Evaluating crevice-corrosion resistance in the laboratory required the development of a suitable coupon configuration. Figure 21 shows a test coupon made up of two sheet pieces held together with a hem flange 180° bend, similar to the design used to seal the bottom of car door skin panels. The two-piece test panel is exposed to internal condensate solutions or external road salt mixtures and, after the appropriate cycles, can be pulled apart, cleaned as described previously, and pit depths measured by a pointed micrometer or calibrated microscope. The two sheet samples making up the crevice test panel can be of the same alloy or of mixed materials, which adds the possibility of a galvanic corrosion contribution.

Table 6 shows crevice-corrosion pit depths after 10 weeks of cyclic condensate exposure. The cyclic test incorporated a weekly 1 h heating of 315 °C (600 °F), followed by daily spraying with the synthetic condensate (450 ppm chloride, 2000 ppm sulfate, and pH 2.5) and a 90 min drying cycle. After the dry period, the hem flange coupons were put in a humidity cabinet for 22.5 h of 60 °C (140 °F)/85% RH. Each weekend, samples remained in the humidity. After 10 weeks of this routine, the hem flange pieces were pulled apart, cleaned, and the average of the ten deepest pits determined. For each alloy, pits were

Fig. 21 Sheet-metal crevice-corrosion hem flange coupon designed for laboratory corrosion tests where both crevice and boldly exposed surface areas are created. With two samples, the test permits the mixing of base metal alloys.

Table 6 Synthetic muffler condensate pit depth after 10 weeks				
Alloy	Boldly exposed area(a)		Crevice area(a)	
	mm	in.	mm	in.
T409	0.43	0.017	0.25	0.010
T439	0.08	0.003	0.18	0.007
430M	0.13	0.005	0.13	0.005
18Cr-Nb	0.03	< 0.001	0.36	0.014
AL409	0.08	0.003	0.13	0.005

(a) Average depth of ten deepest pits

measured within the crevice area and on the boldly exposed surfaces. Comparing pit depths to muffler surveys from the salt belt of the U.S. Northeast revealed that approximately 1 week of this cyclic test was the equivalent of 6 months service in the field.

A comparison of Table 6 bold exposure and crevice pit depths shows the crevice depths to be deeper than or equal to the boldly exposed areas for all alloys except 11%Cr 409. The lower general corrosion resistance of this 11%Cr alloy appeared to cause the crevice opening to fill with oxide debris and choke off the corrosion reaction. While T409 showed the deepest pitting, the 17%Cr T439, the 19%Cr 430M, and the aluminum-coated 409 were more resistant and essentially equivalent to each other.

Intergranular corrosion (IGC), while infrequent, has been found in exhaust applications, generally in the cold end of the system where corrosive liquids are more prone to interact with weld HAZ areas. Ferritic stainless alloys, like their austenitic 300-series counterparts, can be sensitized from improper heating that results in the formation of chromium-rich carbides ($M_{23}C_6$) along grain boundaries and the creation of chromium-depleted base metal areas adjacent to the grain boundaries. These lower-chromium grain-boundary areas are prone to intergranular attack from corrosive liquids. With a lower solubility for carbon compared to 300-series austenitics, the ferritic stainless alloys can be sensitized at lower levels of dissolved carbon as well as with dissolved nitrogen, forming Cr_2N particles. In most exhaust ferritic alloys, titanium or titanium along with niobium are added to reduce soluble carbon and nitrogen contents, making the base alloy and welds more resistant to IGC attack and reducing chances of forming chromium compounds if components are exposed to temperatures in excess of 400 °C (750 °F) (Ref 2). The chromium carbides and nitrides are thought to precipitate up to 900 to 925 °C (1650 to 1700 °F) and will dissolve if heated above 1000 °C (1830 °F) (Ref 3). Unfortunately, the 1000 °C (1830 °F) temperature needed to dissolve chromium precipitates is also high enough to dissolve some (titanium, niobium) carbonitrides, putting interstitial elements back into solution. This soluble carbon and nitrogen can reprecipitate as chromium compounds if, after high-temperature exposure, cooling rates through the red heat zone are too fast for more stable titanium and niobium precipitates to form. With soluble carbon and nitrogen present, exposure temperatures of 705 to 900 °C (1300 to 1650 °F) will lead to grain-boundary chromium precipitate formation. However, above 705 °C (1300 °F), the diffusion rate of chromium in the ferritic stainless base alloy is high enough to replenish chromium-depleted regions adjacent to grain boundaries. No IGC would be expected. Exposure temperatures between 400 and 705 °C (750 and 1300 °F) will also lead to chromium carbide and nitride formation, but chromium-depleted base metal grain-boundary areas will not be replenished,

and IGC is possible if such regions are exposed to moisture and chlorides.

With ferritic stainless alloys, the greatest concern of IGC comes during welding. Stoichiometric calculations predict that the minimum stabilizer needed to remove soluble carbon and nitrogen contents is:

$$\%Ti \text{ min} = 4(\%C) + 3.5(\%N)$$

$$\%Nb \text{ min} = 7.75(\%C) + 6.65(\%N)$$

Hydrocarbons on the steel surface due to lubricants used in component production can provide a source of potential carbon during welding operations. Austenitic filler metals in gas metal arc (GMA) (nonstandard term is metal inert gas) welds can bring higher soluble carbon and nitrogen levels into the weld pool and mix with the ferritic base alloy. The ferritic weld pool is at risk for nitrogen pickup if shielding gas coverage terminates while the weld pool is still at high temperatures. With these added risks, stabilizer levels slightly in excess of minimums have been found desirable. In marginally stabilized ferritic welds, there is the added concern that rapid cooling of the weld may not give enough time for the carbon and nitrogen to be completely combined with titanium/niobium before some chromium compounds begin forming at the lower temperatures.

With the ultralow levels of carbon and nitrogen possible with vacuum oxygen decarburization and some argon oxygen decarburization melting practices, some stabilization ratios even call for a minimum amount of stabilizer regardless of interstitial levels. While some excess stabilizer is desirable, excessive levels of titanium or niobium are felt to be detrimental to weld toughness. A balance is needed. The dual use of titanium and niobium is considered by some to be a way to obtain such a balance. Weld ductility with titanium- or titanium + niobium-stabilized base alloy ferritics is normally considered acceptable, although not as good as the base metal. Experience with niobium-only stabilized melts has shown that autogenous gas tungsten arc welds tend to have a more dendritic cast structure, with reduced formability and toughness. Titanium nitride (TiN) forms at higher temperatures than either titanium carbide (TiC) or niobium compounds. It is thought that these nitrides form in the melt and act as nucleation sites for ferritic grains. If a ferritic stainless were to have only one stabilizer to remove carbon and nitrogen content, titanium would be the best choice. Recent advances in stainless melting technology have largely overcome earlier concerns that titanium stabilization will lead to unsightly and abrasive surface streaks of TiN.

Laboratory tests to evaluate ferritic stainless alloys for IGC are covered by ASTM A 763 (Ref 4). As a screening tool to look for susceptibility of intergranular attack with stabilized ferritic alloys, the electrolytic 10 wt% oxalic acid test (practice W) can be used. If one or more grains are found completely surrounded by ditched (corroded) grain boundaries, the proce-

dures then calls for additional testing using the more definitive practice Z. This practice calls for 24 h of boiling in copper-copper sulfate ($Cu-CuSO_4$) solution acidified with 16% sulfuric acid (H_2SO_4). After boiling, the samples are bent 180° around a diameter equal to 4*t*, where *t* is the sample thickness. Examined at 5 to 20×, the bent outer-diameter surfaces must not show cracks in order to be considered resistant to IGC. It bears mentioning that the practice Z test is designed for alloys with a minimum of 17 to 18% Cr. T409, with its nominal 11% Cr addition, will be heavily attacked by the $Cu-CuSO_4$ solution and, at times, dissolved in 24 h, depending on initial sample thickness. To evaluate IGC in stabilized 11 to 12% Cr alloys, several modified practice Z procedures have been used but are not incorporated into the ASTM standard. In one practice Z modification, the standard solution was used, but the test cycle was reduced to 16 h of exposure in a 30 °C (85 °F) solution. A second, modified cycle exposed the samples to boiling solution for 20 h but lowered the H_2SO_4 solution strength to 0.5 wt%. Reducing the aggressiveness of the test solution permits comparisons of the 11 to 12% Cr alloys without generally attacking and dissolving the base metal.

When T409 became the material of choice for catalytic converter shells in the mid-1970s, the 11% Cr ferritic was melted to a stabilization specification of 6×C minimum. In those days, the carbon and nitrogen levels were each close to 0.03%, and titanium levels ranged from 0.3 to 0.5%. With advances in melting, the carbon levels were reduced to typically less than 0.015%, and nitrogen levels fell to 0.02%. With lower carbon content, titanium could be reduced and meet the 6×C minimum. Unfortunately, with no nitrogen factor in the specification and TiN forming in the melt, marginally stabilized 409 melts were produced. Failures such as the one shown in Fig. 22, while rare, were encountered. Here, a 409 tail pipe GMA welded to a 409 rear muffler head fractured in the HAZ after several years of driving service in Canada. A micrograph of the weld break in cross section shows the intergranular nature of the failure.

In response to failures like the one in Fig. 22, ASTM International and the stainless steel producers redefined the minimum stabilization in 409 to include both carbon and nitrogen. ASTM International recognizes three T409 stabilization specifications (Ref 5):

$$Ti \text{ min} = 6(C + N)$$

$$Ti \text{ min} = 8(C + N) \text{ and } 0.15\% \text{ min}$$

$$(Ti + Nb) \text{ min} = 0.08 + 8(C + N)$$

Since adopting the higher stabilization minimums, no major IGC exhaust failure incidences have been reported.

Galvanic corrosion due to the coupling of dissimilar metals in the presence of a corrosive solution is the last form of corrosion found to have occurred in exhaust system components. Fortunately, like intergranular attack, exhaust designers have learned from experience, and

premature failures from this type of attack have been eliminated.

In galvanic or bimetal corrosion, the two dissimilar metals have different corrosion potentials for the solution involved. When electrically coupled in the presence of the conducting solution, current flows between the metal pair. The more noble or corrosion-resistant material will experience a reduced rate of attack and become the cathode. The less noble alloy becomes the anode and undergoes more rapid corrosion, actually sacrificing itself to protect the more noble material of the pair. The rate of weight loss or pitting for the anodic metal in the couple depends on how far apart the two materials are in the electromotive force series for the corroding liquid involved, as well as the relative size difference of the anode and cathode. A small anode area coupled to a large-area cathode is the worst possible combination, leading to rapid attack of the less noble alloy. Earlier in this article, one form of galvanic corrosion was alluded to in the description of the galvanic protection that aluminum coatings provide when hot dip coated onto carbon and stainless steel substrates. Here, the aluminum outer layer sacrifices itself for the steel substrate if a scratch or cut edge is encountered. In this type of application, the area of the aluminum anode is large and the steel cathode small. Protection is then provided with a minimum of attack to the less noble aluminum layer.

To see the worst form of exhaust system galvanic corrosion, one must go back to the days (prior to 1995) when exhaust designers mixed the stainless 11%Cr T409 alloys with straight

Fig. 22 Tail pipe and muffler end cap, both of 409, that failed by intergranular corrosion after driving service in Canada. Cross-sectional photo at bottom is 50 \times . Base alloy had Ti/(C + N) ratio of 5.8.

aluminized type 1 carbon steel (ALT1). One scenario involved upgrading the corrosion resistance of mufflers by specifying 409 while continuing to call for ALT1 for the attached intermediate pipe. The two dissimilar metals were joined with a GMA weld using a stainless 409Nb weld filler. Exposure to corrosive road salt solutions on one surface and muffler condensate on the other created a galvanic cell. The aluminum coating on the carbon steel substrate sacrificed itself to protect the 409 muffler shell and weld (Fig. 23). With time, the aluminum was stripped away, revealing the underlying carbon steel base metal. With extended exposure times, the loss of aluminum became great enough that a carbon-steel-to-409 couple was established. The less noble carbon steel now attempted to protect its stainless material mate. A corrosion failure next to the weld soon ensued. A rough rule of thumb would predict that 409 pipes to 409 muffler shells should last a minimum of 5 to 7 years without perforation. The ALT1 tubes and shells, depending on the type of protection used on welds, could survive 3 years or more under the car. The aforementioned dissimilar-metal galvanic couple was predicted to fail in the coated carbon steel in 18 to 24 months of service.

In a similar problem, Fig. 24 shows an internal view of an exhaust muffler taken off of a vehicle with less than 16,000 km (10,000 miles) of driving. The muffler designer mixed 409 internal

Fig. 23 Galvanic corrosion when mixing muffler materials. Aluminum sacrifices itself to protect the 409 stainless steel, exposing the carbon steel substrate.

Fig. 24 Internal view of muffler with 14,500 km (9,000 miles) of service. Condensate galvanic corrosion between the 409 stainless baffles and ALT1 shell has destroyed the wrap.

baffles and tubes with an ALT1 exterior shell to take advantage of the coated carbon steel cosmetic resistance to early red rusting. Unfortunately, the galvanic cell created by the stainless baffles contacting the inner surface of the ALT1 shell in the presence of corrosive condensate liquids led to accelerated galvanic attack of the shell and a linear perforation of the shell under the baffle in a very short driving time.

Failures similar to the two previously described examples occurred in the 1980s and early 1990s as car makers and OEM designers struggled to upgrade cold end exhaust system durability by selectively mixing stainless components with the old standard ALT1 carbon steel. However, with the arrival in 1995 of the 3 year/58,000 km (36,000 mile) warranties, the replacement of coated carbon steels in OEM exhausts accelerated, with the final replacement occurring in one major truck line in model year 1996.

Since the switch to all stainless, catastrophic galvanic corrosion failures have essentially disappeared, although dissimilar-metal couples still exist. The use of aluminum-coated 409 for cold end cosmetic applications has led to the frequent coupling of a bare stainless component to an aluminized one. Once again, the aluminum layer sacrifices itself to protect its bare stainless neighbor. Fortunately, in this instance, as the aluminum and underlying iron-aluminum intermetallic layer are removed, a stainless substrate is revealed with far better durability than was found with coated carbon steel.

Early in the development of aluminum-coated 409, corrosion studies found that the intermetallic iron-aluminum diffusion layer that forms when the hot dip Al-10%Si layer is applied to the 409 substrate is anodic or protective to the base alloy. On aluminized carbon steels, the alloy layer, once the free aluminum is removed, offers no additional corrosion protection. Regardless of the substrate composition, red rust will appear once the free aluminum is gone and the iron of the alloy layer is exposed to moisture.

Figure 25 shows a muffler with 27,400 km (17,000 miles) of exposure. The muffler shell or

Fig. 25 Muffler with AL409 wrap and bare stainless belly band and end cap (right side of image). After 27,400 km (17,000 miles) of driving service, the band and muffler end plate have led to galvanic attack on the aluminum coating of the wrap.

wrap was made of AL409, while the end cap (on the right) and the belly band were bare stainless steel. Note that the band and cap are not heavily rusted or discolored (the benefit of galvanic protection), while the AL409 shell areas adjacent to the cap and belly band show dark-gray stripes where free aluminum has been galvanically removed, exposing the underlying alloy layer. With additional time, those exposed alloy layers will begin showing red rust. In a similar vein, the muffler and tail pipes shown in Fig. 26 were half constructed of bare 409 and half AL409. The muffler/pipes were installed on a vehicle and driven 6 months, with daily spraying with a salt solution. Cosmetically, the aluminum coating made a great difference. The circumferential GMA weld (409Nb) joining the muffler halves further demonstrates the galvanic benefit of the aluminum coating. On the aluminized muffler half, a band of aluminum has been galvanically removed, sacrificing itself to protect the weld bead and bare 409 shell on the other side of the weld. On the bare 409 muffler half, a strip of 409 with far less superficial red rust is apparent, the benefit of the protective nature of aluminum.

From a galvanic standpoint, bare stainless alloys can be coupled to each other with but a minimal dissimilar cell being established. One exception to this is the muffler section shown in Fig. 27. Here, a double-wall muffler used a thick inner shell of 409 for support and a thinner

outer layer of 439 for better cosmetic corrosion resistance. Intrapipe seepage of condensate and road salts caused the 409 to corrode, probably a little faster than normal, because it was the less noble member of the 409/439 couple. With time (103,000 km, or 64,000 miles, of driving), the corrosion product on the 409 surface grew in volume, exerted pressure on the thinner 439 outer wrap, and forced a mechanical fatigue tear. In Fig. 27, a portion of the 439 skin has been cut away to reveal the underlying corrosion debris, but some of the 439 tear is still visible running parallel to the muffler long dimension.

Fig. 27 Galvanic corrosion between a T439 outer muffler wrap and inner T409 shell caused corrosion debris to build up between the layers and split the outer wrap. Crack visible in wrap despite section removal to show corrosion debris

Fig. 26 Muffler with wrap and heads half made of bare 409 (bottom portion) and half of AL409 (top portion) and test driven 27,400 km (17,000 miles). Bare 409 gas metal arc weld and band of bare 409 adjacent to the weld galvanically protected by aluminum coating

In concluding this section on dissimilar-metal galvanic couples, the story would not be complete without discussing the two areas of OEM exhaust systems that still use some bare carbon steel. Solid rod hangers 10 to 15 mm (0.39 to 0.59 in.) in diameter, to attach exhaust systems to the underbodies of vehicles, and connecting flat flanges 9.5 to 12.7 mm (0.375 to 0.500 in.), used mainly between hot end exhaust components, are still frequently made of low-carbon steels occasionally sprayed with glass film paints to impart some barrier corrosion protection. While such carbon steel components would be anodic when mated to stainless materials, exhaust designers have felt the heavy bare steel thicknesses would allow these parts to meet the warranty targets. If not carbon steels, such parts have been made from wrought austenitic stainless alloys such as 304L, a nickel-modified 409 (409Ni) for improved cold weather toughness, or

Fig. 28 Galvanic corrosion of solid carbon steel hanger rods after 1.5 years of driving service in salt belt. Muffler end plate and sheet-metal hanger are 18Cr-Nb.

Fig. 29 Exhaust system schematic with major corrosion concerns by component

from powder metallurgy stainless components. Standard exhaust ferritic alloys, such as 409 or 439, have been found to suffer from lower-temperature brittle impact fractures when produced to these heavier flange/hanger rod thicknesses.

Even assuming the bare carbon steel flanges or rod hangers have the corrosion durability to meet warranty targets, galvanic corrosion of these components can lead to cosmetic corrosion concerns. Figure 28 shows the muffler end plate and tail pipe of an 18%Cr exhaust section. For attachment purposes, a stainless sheet-metal bracket has been welded to the muffler cap and attached to rubber grommets with bare carbon steel rod hangers. After 1.5 years of service, the attack on the carbon steel rods is obvious. When and if this system fails, the hanger will probably be the most likely point. However, even prior to an actual system failure, concern could be expressed that iron oxide red rust from the hanger may cover the attachment bracket and even bleed down onto the muffler face or tail pipe.

Conclusion

In concluding this survey of corrosion in modern automobile exhaust systems, a schematic (Fig. 29) of a typical exhaust system is

once more reproduced, and identifying arrows are added where one would expect to find the various forms of corrosion discussed previously. While today's (2006) typical system is easily capable of 7 to 10 years of durability from a corrosion standpoint, the materials needed for a 15 year exhaust life are probably already available, if engineers can optimize designs to minimize the corrosion mechanisms discussed in this article.

ACKNOWLEDGMENT

Appreciation is expressed to Richard Strait, Principal Marketing Engineer at AK Steel, who developed many of the corrosion tests and conducted most of the failure analyses and field surveys reported or referred to in this article.

Engine Coolants and Coolant System Corrosion

Aleksei V Gershun and Peter M Woyciesjes, Prestone Products

A GOOD ENGINE COOLANT must minimize the degradation of nonmetals and prevent the corrosion of the metals in the cooling system. Excessive deterioration of any material can lead to a loss of coolant from the cooling system, to a reduction in the strength of a material or component, and to the subsequent malfunction of a part leading to engine failure. Even minor deterioration can cause deposits to form on heat exchanger surfaces, reducing heat transfer and/or restricting coolant flow in the radiator and heater core tubes and ultimately to a plugged heater core or to overheating of the engine from a plugged radiator.

Antifreeze History

As automobiles developed and liquid cooled engines became more commonplace in the period 1910 to 1925, one of the first cooling system problems to develop was leakage. Roadways were extremely rough and leaks caused by vibration were relatively common, particularly at radiators.

In the early days, car use was generally confined to periods when temperatures remained consistently above freezing because of difficulties with cold weather starting and the lack of heat in the passenger area. Cars did not have heaters and often were equipped only with side curtains, making driving very uncomfortable. In cold climates, cars were usually stored in winter. As engines and lubricants improved, heaters were developed and glass side windows became the rule and more winter driving was attempted. This required an engine coolant that would not freeze in the cold months. Many compounds such as honey, sugar, molasses, and ethyl alcohol were used. Alcohol became the most satisfactory engine coolant with "antifreeze" properties. Despite good cooling ability, alcohol had significant drawbacks of boilaway, odor, corrosion, and flammability. The car owner was perpetually uncertain as to the level of freezing protection.

The antifreeze business, as we know it today, began with the marketing of ethylene glycol antifreeze in 1927. It provided consumers with

the first true engine coolant/antifreeze. It provided the engine with the necessary boil-over protection in the hot months and freeze-up protection in the colder months.

Over the next decades, ethylene glycol coolants saw many advances in inhibitor technologies. Glycol coolants continued to provide better and longer-lasting protection to the cooling system.

United States automakers, Ford Motor Company, General Motors, and DaimlerChrysler, began installing a 50% water and 50% ethylene glycol coolant solution into their new vehicles. This led to the emergence of engine coolant/antifreeze as a year-round functional fluid, making it as important as engine oil or automatic transmission fluid.

The early 1970s marked a significant turning point in engine design and inhibitor technology for engine coolants. Engine coolants were reformulated to incorporate the unique, patented silicone-silicate copolymer, which greatly enhanced inhibitor effectiveness, particularly for aluminum cooling system components. Lighter-weight aluminum components were starting to become more prevalent in vehicle design, particularly in the engine cooling system. The new silicate-silicone coolant technology was ideally suited to protect engines from the increased operating temperatures created by higher-opening temperature thermostats, exhaust emission controls, trailer hauling, air conditioning, and other power options.

In the late 1980s, the need for globalization of coolant technologies to meet a single performance standard was addressed. With concerns of using phosphates in Europe and concerns of using borate and silicate in engine coolants in Asia, the direction of coolant technology started to shift to a coolant that did not contain any phosphate, silicate, or borate. Organic acid-based inhibitor technologies filled this niche nicely. In 1995 General Motors was the first U.S. manufacturer to switch to organic acid coolant technology as its original factory fill coolant. Since then, Ford and Chrysler have changed to hybrid organic acid technology, which combines silicate technology with organic acids.

What do we have in store for the future? Engine coolant technologies still face many challenges. With the desire to continue to go to lighter materials in the cooling system such as magnesium components, inhibitor technology will change to address the potential corrosion issues of these new materials. Furthermore, advances in vehicle design and technology, such as new brazing technologies for heat exchangers (radiators and heater cores) or new engine/motor designs (fuel cell technology or heavy-duty engines with new exhaust gas recirculation (ERG) systems), will require engine coolant technology to continue to change to keep up with these improvements.

Cooling System Functions

The cooling system has several functions, but the most important is controlling the temperature of the internal combustion engine. Under load, an engine can theoretically produce enough heat to melt an average 90 kg (200 lb) engine block in 20 minutes. Even in normal driving conditions, combustion gas temperature may be as high as 2500 °C, (4500 °F), and lubricated parts, like pistons, may run 110 °C (200 °F) or more above the boil point of water. No matter what time of year, there is a safe high-operating temperature that helps provide maximum engine performance with the least engine wear. It is the function of the cooling system to maintain this operating temperature and reach it as quickly as possible during summer and winter.

The cooling system provides heat to the passenger compartment because the hot coolant passes through the heater core. As fresh air comes in, the heater core warms it before it enters the passenger compartment. If the vehicle uses the same ducts and controls for the heater, warm air from the heater can also be used to regulate the temperature of the chilled air released by the air conditioner.

Another function of the cooling system, especially in vehicles with automatic transmissions, is to control the temperature of the transmission fluid carried to and from an oil cooler

in the radiator by oil lines connected to the transmission.

The primary function of the coolant is to maintain the optimum operating temperatures of the engine by preventing the engine from boiling over by carrying excess heat away from the engine and by preventing freezing in the winter. Vehicles today have higher operating temperatures because of air conditioners, antipollution devices, automatic transmissions, new under-the-hood materials, and increased engine cooling loads. Smaller vehicles have higher cooling loads because the engine works at a higher percentage of its capacity to power the vehicle. These higher temperatures demand a coolant with a boiling point higher than water, so vehicles come from the factory with a mixture of coolant concentrate and water generally 44 to 55% coolant concentrate. The engine coolant water mixture should be maintained within this range, with 50% being optimal.

A good coolant also has inhibitors that fight rust, corrosion and other cooling system problems, which can result in clogged radiator and heater core passages that eventually reduce the efficiency of the cooling system. This can lead to overheating of the engine and engine failure. The correct mixture of coolant and corrosion inhibitors will prevent this.

The cooling system must be able to adequately cool a vehicle traveling at 125 mph in 50 °C (120 °F) temperatures in Arizona. The same vehicle should not experience thermostat cycling problems when driving in -29 °C (-20 °F) weather in Minnesota.

Achieving optimal engine performance requires careful balance between the coolant and the various cooling system components. The coolant and cooling system work together to control the temperature of the engine. Cool metal temperatures are good for horsepower, but bad for hydrocarbon emissions. Higher temperatures are good for reducing hydrocarbons, but bad for nitrogen oxide emission (NOx) and may also cause spark knock. High temperatures are also good for reducing oil viscosity, lowering friction, and reducing fuel consumption, up to a point. Very high temperatures quickly degrade

oil life, and temperature gradients must also be controlled. High gradients can lead to thermal distortion, thereby degrading performance and reducing engine life.

Optimizing coolant temperature requires knowledge of the engine operating conditions. Some factors that affect metal operating temperatures include:

- Coolant velocity
- Coolant temperature
- Coolant pressure
- Coolant composition
- Coolant concentration
- Engine load
- Amount of entrapped air in the system
- Water pump size
- Flow restrictions
- Heat exchanger size and design

All of these factors must be considered. Every component in the cooling system affects other component performance. For example, a change to the fan clutch can cause a water pump failure; a change in the size of the radiator tube can correct an overheating engine.

The cooling system needs to be designed, constructed, and maintained as a system. Individual components cannot be developed independently of each other. The system must operate under the worst conditions the customer will subject it to.

Cooling System Operation. When a gasoline engine is started, fuel and air are pumped into the combustion chamber and ignited by the spark plug, and the coolant pump begins circulating coolant through the engine block. The combustion process generates heat while the coolant system removes heat and maintains the optimum engine temperature.

Initially, coolant goes through the cylinder block from the front to the rear (Fig. 1), circulating around the cylinders as it passes through the cylinder block. At the rear of the cylinder block it passes up to the cylinder head through openings in the cylinder head gasket that seals the cylinder block and cylinder head together.

The coolant then circulates from the rear to the front of the cylinder head through passages

around combustion chambers. These passages permit extra cooling of high-heat areas such as the spark plugs and exhaust valve seals.

As the coolant leaves the cylinder head it comes in contact with the thermostat. Until the coolant bulk temperature reaches ~82 °C (180 °F) the coolant will continue to circulate through the engine block. When the coolant reaches this temperature, the thermostat will open and send hot coolant to the radiator. The coolant enters the radiator at the tank inlet at the top and flows across or down through the tubes in the core, where it is cooled, and then flows to a tank on the other side of the core. From there it returns to the engine via the coolant pump.

Materials. Alloys of cast iron or cast aluminum are used for cylinder blocks, cylinder heads, intake manifolds, coolant pumps, and coolant outlets. Wrought brass or wrought aluminum are used for radiators and heater cores. For brass radiators and heater cores, high or low lead solders are used to join the components. Stamped steel is frequently used for small components such as core hole plugs, coolant pump housing closures, and coolant pump impellers.

Synthetic elastomers, such as ethylene propylene diene monomer (EPDM), are used for hoses to provide flexible connections from the engine to the radiator and heater core. Rigid plastics, such as high-density polyethylene and reinforced nylon, are typically used for coolant recovery reservoirs, and plastic radiator or heater tanks, respectively.

Cylinder head gaskets are embossed steel shim construction or silicone elastomer composition overlaid on a steel core and reinforced with steel grommets. Occasionally, stainless steel may be used for embossed shim cylinder head gaskets where extra corrosion resistance is desired.

The coolant comes in direct contact with all of these construction materials, and the combination of materials and coolant is frequently associated with corrosion problems or failures with cooling system components. In this respect, the coolant should be recognized as a critical material and a full-time functional fluid.

Components. The major components of a cooling system are as follows.

Heat Exchanger. The radiator and heater core consists basically of a series of small tubes and fins surrounded by air passages. Hot coolant from the engine flows through the tubes and is cooled by air flowing around them. Heater cores are very similar to radiators in their design and construction. To prevent the heater core from experiencing excessive flows, some vehicle manufacturers place a variable restriction in the coolant circuit just ahead of the heater core.

The coolant fan draws cooling air in from the outside through the radiator core air passages to cool the radiator during idling and low-speed operation.

The coolant pump (often referred to as the water pump) forces coolant through the engine block and the engine coolant components. To provide adequate engine cooling for a typical

Fig. 1 Circulation and components of the cooling system. A, heater hose; B, heater control valve; C, thermostat; D, radiator hose; E, overflow reservoir; F, heater core; G, engine; H, coolant pump; I, fan; J, radiator

passenger car, the pump may have to circulate as much as 28,000 L (7397 gal) per hour.

The fan belt is extremely important to the operation of the vehicle cooling system because it drives both the fan and coolant pump.

The thermostat is a heat-operated valve that controls the amount of coolant that flows from the engine to the radiator. In cool weather or for light driving when maximum cooling is not needed, the thermostat is nearly closed.

Pressure Cap. Cooling systems are built to function at high temperature and pressure. The radiator pressure cap controls the pressure that builds up in the cooling system at high operating temperatures. This pressure, in turn, raises the boiling point of the coolant. A pressure cap that's working properly reduces the chance of boiling and loss of coolant through overflows. The correct pressure cap is determined by car model and year and can be found in the owner's manual.

Radiator hoses and coolant hoses are flexible tubes that are used to connect the engine components. The basic hose design consists of three elements. There is an inner hose (tube), reinforcement knit (yarn), and a protective outer layer (cover). The coolant hoses are made of elastomers that must be designed to resist heat and coolant; most hoses use EPDM, the most cost-effective option. For high-heat applications, silicon hoses are available. There are several materials that are commonly used to reinforce hoses: nomex, kevlar, rayon, polyester, or nylon. The yarn that is used in the reinforcing knit can be wound in several different ways: spiral wrap, plain stitch, plain radial, lock stitch, and braid.

Corrosion

Corrosion is the destructive electrochemical reaction between a metal or metal alloy and its environment. Vehicle manufacturers around the world install inhibited engine coolant in new cars and trucks to protect the cooling system from corrosion. They recommend all subsequent coolant changes or cooling system "topoffs" be done with a well-inhibited engine coolant rather than just water or water with an added rust inhibitor.

Drivers are frequently interested in how much freezing protection they are getting. Most vehicle manufacturers are not as concerned with freeze point because most coolants on the market are glycol based and provide adequate protection. Manufacturers are more concerned with the degree of corrosion protection for the various metals found in automotive cooling systems: aluminum alloys, cast iron, copper, brass, steel, and various brazes and solders.

The basic mechanisms involved in cooling system corrosion are no different from those in other systems and, therefore, methods of control are similar. Metals are corroded by direct chemical attack as a result of electrochemical processes. When certain conditions exist, cavitation-erosion-corrosion can also occur.

Various forms of corrosion that occur in cooling systems are:

- Uniform corrosion
- Galvanic corrosion
- Crevice corrosion
- Solder bloom
- Pitting corrosion
- Intergranular corrosion
- Erosion corrosion
- Cavitation corrosion

Each form of corrosion is described as it affects cooling system corrosion failures.

Uniform corrosion of a cast iron block in an acidic, used coolant environment is an example. Uniform corrosion is preferred from a technical viewpoint because it is predictable and spread over a large surface (not localized). Cooling system components can be designed to withstand general surface corrosion.

Galvanic corrosion will occur if two different metals are immersed in the conducting coolant and are connected by an external circuit to permit a flow of current. In this event, the more active metal, based on its position in the electromotive force series, will usually act as an anode and dissolve as the more noble cathode accepts electrons through the external circuit. The extent of galvanic corrosion depends on many things, such as the magnitude of galvanic potential, conductivity of the fluid (coolant), area ratio of the anode and cathode, surface conditions of the coupled metals, and coolant flow.

Galvanic potential is related to the magnitude of the current produced by coupling dissimilar

materials exposed to a common electrolyte. The potential depends on the metals that are coupled and on the characteristics of the electrolyte to which the metals are exposed. A galvanic series has been developed experimentally that lists many commonly used metals according to their galvanic potential in flowing seawater (see "Reference Information" in volume 13B, *Corrosion: Materials*). Although this series is specific to aerated seawater, differences with other aqueous solutions are often minor, i.e., depleted engine coolants, coolants that have been overdiluted with water, and coolants that have degraded.

Crevice Corrosion. The corrosion rate of an alloy is often greater in the small sheltered volume of a crevice. This crevice may be created by the form of the fluid channel, a mechanical seam, a fastener (bolt, rivet, washer) of the same or different alloy, a deposit (sand, corrosion product, or other insoluble solid), or a non-metallic gasket or packing. If the crevice is made up of differing alloys or if the deposit is conductive, crevice corrosion may be further complicated by galvanic effects.

Severe crevice corrosion damage has been observed at hose connections with aluminum coolant outlets, pump inlets, and pump bypass fittings. In most cases, the problem is caused by fittings, where the hose and hose clamp are unnecessarily too far down on the connection, as shown in Fig. 2. Even if perforation does not occur, the corrosion products formed in the crevice can interfere with proper sealing of the hose, causing coolant leakage. Positioning the hose clamp tightly against the bead usually prevents such failures.

Engine block core hole plugs fail from perforation caused by crevice corrosion if they are not installed properly (Fig. 3). If the core-hole plugs located on the outer walls of the cylinder block are not inserted flush to the coolant jacket, deposits build on the core-hole plug, setting up crevice corrosion. Perforation of the thin steel plug, followed by coolant leakage, is the inevitable result. Prevention is achieved simply by locating the inner face of the plug flush with the coolant jacket wall.

In certain radiator and heater core designs, a turbulator is inserted in the tubes to enhance heat transfer. If the turbulator is located in tight

(a)

(b)

Fig. 2 Crevice corrosion can occur at hose connections. (a) The right and wrong way to position a hose clamp on a coolant outlet. (b) Severe crevice attack of an aluminum coolant outlet due to incorrect hose positioning

contact with the inside diameter of the tube, crevice corrosion can be initiated at the fixed contact sites. This can be avoided by ensuring that design-in minimum clearances are met to ensure against crevice sites.

With recently developed aluminum radiators and heater cores, there is a trend to employ plastic inlet and outlet tanks that are gasketed and clamped to the heater plates. Crevice corrosion can ensue if deep crevices are formed at the interface of the gasket and the aluminum heater plate.

Solder Bloom. Brass radiator soldering techniques and materials selection have a direct bearing on solder corrosion and clogging at the tube-to-heater plate joint. Lead solders are used in manufacturing cores and complete radiators because of their high temperature strength and melting point. The lead content makes the alloy difficult to inhibit from forming voluminous corrosion products, i.e., solder bloom. If excessive amounts of solder are deposited around the tube joint, and if the interior of the tube opening is wetted by the solder, there is a better chance that partial clogging of the tube opening will occur after 3 or 4 years of service (Fig. 4). Extended use and/or dilution of the coolant increases the probability of clogging.

Pitting Corrosion. There are a number of design and material factors with both brass and aluminum radiators that affect inherent resistance to pitting corrosion. High flow rates through the tubes can generate impingement erosion forces sufficient to erode passive or protective films and cause pitting perforation. This type of attack has been observed for down-flow radiators just below the entrance of the tube in both aluminum and brass radiators.

Contamination of the coolant with aggressive ions such as chloride and sulfate tend to

exacerbate the problem by breaking down protective films or by preventing their formation. Direct attack can also occur by the deposition of a more noble metal on one lower in the electromotive series. For instance, the deposition of copper on the more electronegative aluminum can initiate pitting corrosion that results in perforation of the radiator tubes.

Pitting corrosion by definition is confined to small areas; the highly localized corrosion results in pits that can lead to early failures in the thin metal sections of radiator tubes and heater cores. Similar attack in the engine block would not be as critical considering the greater thickness of metal (Fig. 5).

Intergranular Corrosion. Reactive impurities may segregate, or passivating elements such as silicon (in aluminum alloy) may be depleted at the grain boundaries. As a result, the grain boundary or adjacent regions are often less corrosion resistant. Preferential corrosion at the grain boundary may be severe enough to drop grains out of the surface. Intergranular corrosion (IGC), sometimes called intergranular attack, is a common problem in many alloy systems, including aluminum alloy with cladding materials found in cooling systems.

Cladding materials consisting of aluminum-silicon alloy have a noble electrode potential and are severely attacked at the aluminum and silicon boundaries. The IGC is caused by cathodic-type of galvanic action based on silicon diffusion or precipitation along the boundaries. Relatively shallow silicon diffusion tends to produce IGC that spreads only on the surface of materials. The deeper silicon diffusion produces more severe intergranular corrosion in the material thickness direction.

Erosion Corrosion. High velocity fluid flow can result in erosion-corrosion (Fig. 6). Design

factors, materials of construction, and a depleted coolant can further aggravate this damage. A coolant flowing slowly through a component may show low or modest corrosion rate, but rapid movement of the same fluid can physically erode and remove the protective film, exposing reactive alloy beneath, and accelerating attack. Low-strength alloys that depend on a surface oxide layer for corrosion resistance are most susceptible. The attack generally follows the directions of localized flow and turbulence around surface irregularities.

Cavitation corrosion is a complex phenomenon involving mechanical damage from the pressure shock waves or jets, created by collapsing vapor bubbles in the coolant. The cavitation process begins with the coolant being converted to vapor at a high temperature or a low pressure point. Subsequently, when temperature

decreases or the pressure increases, the vapor bubbles collapse at very high rate and produce intense shock waves or jets. These waves radiate out pounding the nearby metal surface and causing the surface to erode or pit. Cavitation can also cause the fracture of brittle materials and fatigue failure of ductile metals.

Aluminum water pumps are vulnerable to cavitation-erosion-corrosion in the presence of improperly inhibited, depleted, or diluted engine coolant. The extent of damage and tendency to perforate are also influenced by the cooling system and coolant pump design. Internal configurations that concentrate large pressure gradients (sudden pressure changes) can cause localized pitting and erosion, which can result in decreased pump performance and potential perforation failure of the pump body or cover (Fig. 7).

Aluminum cylinder heads are exposed to potential cavitation corrosion conditions in the high-heat flux areas where nucleate boiling is generated (Fig. 8). Here again, coolant inhibitor type, glycol concentration, degree of inhibitor depletion, materials selection, and component design have a major effect on the extent of attack. Design deficiencies in terms of flow rate, flow distribution, and surface-to-volume ratios in the coolant jacket passages can increase the intensity of the corrosion damage (Fig. 9).

Further improvements in engine cooling system performance and reliability can be obtained by increased awareness of the following factors:

- Design and materials application should reflect thorough study of specific corrosion mechanisms.

(a)

(b)

Fig. 7 Corrosion perforation of (a) aluminum impeller and (b) aluminum cover of a coolant pump resulting from a used and degraded engine coolant

- Material changes, particularly toward light alloys, should be accompanied by full consideration of differences in properties and design requirements.
- The role of the coolant as a full-time, high-performance functional fluid should be more critically evaluated.
- Consumer and service industry practices should be studied further to assess the opportunity to reduce cooling system failures and increase overall engine performance and service life by using good quality coolant.

Engine Coolant Base Components and Inhibitors

No single component or inhibitor will satisfactorily protect all of the metals in an automotive cooling system. The proper selection of an inhibitor combination depends on such things as the metal used, the composition of the coolant base, flow conditions, environmental temperatures, federal and local regulations, and heat flux at the heat transfer surfaces. Ethylene and propylene glycol are the most commonly used base fluids to provide the necessary boiling and freezing point protection required in vehicles. To these base fluids, an assortment of organic and inorganic inhibitors are added to provide protection against corrosion and to maximize the performance of the cooling system.

Glycols are the principal component of all modern coolants and comprise ~95% of the engine coolant because of their unique ability, when diluted with water, to elevate the boiling point and depress the freeze point of the engine coolant-water solution. Ethylene glycol is the primary glycol used. When diluted to a 50 vol% solution, it will provide boiling point protection to 130 °C (265 °F) (in the cooling system, under a 0.10 mPa, or 15 psi, pressure cap) and freeze-point protection to -37 °C (-34 °F).

This increased boiling point allows a car engine to run hotter while still avoiding the catastrophic coolant loss and potential engine damage that would accompany violent boiling. The decreased freezing point provides the cooling system protection against freeze up and damage to the components due to thermal

expansion of the coolant during the cold winter months.

Buffers. The pH of a coolant depends on the nature of the metal to be protected in the cooling system, as well as the selection of the inhibitors used in the inhibitor package. Some inhibitors initially prefer a high-pH (~10) environment. Ideally, the pH of the coolant should be between 7 and 9 while in use. The buffer prevents the pH of the coolant from drifting up or down from the desired set point. The buffer must neutralize any acids generated by the degradation of glycol or from corrosion processes and consume free hydroxide formed by the corrosion of aluminum alloys. Some common buffers used over the years include borates, phosphate, benzoate, and triethanolamine salts. These buffers have been used by themselves and in combination with each other.

Borates are used in the coolant to provide a buffer solution (pH ~8-9) to prevent the pH from dropping to a range where the corrosion of ferrous metals, such as cast iron and steel, is unacceptably high.

Phosphates (di and mono salts) serve two functions. Their principal function is to buffer the pH of the fluid from dropping to a value that would be corrosive to ferrous metals. It has a wide buffering range, pH 7 to 10. Hydrogen phosphate ion also serves as a primary corrosion inhibitor for aluminum and provides some additional protection for solders and ferrous metals.

Sodium benzoate also has some buffering capability; however, it buffers in the range pH 4 to 6 in contrast to borate and phosphate, which buffer in the range pH 7 to 10. In addition, sodium benzoate serves as a corrosion inhibitor for the ferrous metals, cast iron and steel.

Triethanolamine is used most often to neutralize phosphoric acid to give the triethanolammonium salt in much the same way that sodium hydroxide is used to neutralize phosphoric acid to give the sodium phosphate salts in other formulas. The triethanolammonium ion formed in this neutralization acts as a buffer to prevent the pH of the antifreeze from increasing to a range that would be corrosive to aluminum. The phosphate ion formed in this neutralization acts as a buffer to prevent the pH of the antifreeze from dropping to a range that would be corrosive

Fig. 8 Nucleate boiling-induced cavitation corrosion caused perforation at the exhaust valve port of this aluminum cylinder head.

Fig. 9 Severe cavitation corrosion in an aluminum cylinder head exhaust port manifold

to ferrous metals. Triethanolamine also serves as a primary corrosion inhibitor for ferrous metals in this formula.

Inhibitors. ASTM D 4725, "Standard Terminology for Engine Coolants," defines an inhibitor as a chemical compound added to engine coolant to mitigate cooling system degradation. Following are some common coolant corrosion inhibitors and their functions.

Silicate and Silicones. Silicate is one of the most effective corrosion inhibitors. It is used primarily to provide protection of the aluminum components in a car's cooling system. Silicates also provide protection to other metals, including cast iron and steel. Care has to be taken when using silicate chemistry because the failure to incorporate it properly in a stable form can lead to dramatic corrosion of aluminum components, such as engine blocks, heads, and radiators.

Silicone is one of the most important components of fluids based on silicate technology because it provides for the proper stabilization of inorganic silicate. Failure to add adequate amounts of an effective silicone stabilizer will result in the formation of silicate gels in the coolant concentrate or in the cooling system. This can lead to severe corrosion and flow-related problems due to blockage of narrow cooling system passages in the heater core and radiator tubes.

Triazoles and Thiazoles. These groups of inhibitors are typically used to protect copper and brass components. In engine coolants they are used both by themselves and in combination with each other.

Benzotriazole, commonly abbreviated BZT, is the parent compound of the more-familiar homologue, tolyltriazole. Benzotriazole is classically used to protect copper and brass by forming a tough, protective film over the surface of the metals. It may also protect solder and aluminum, but these mechanisms are not yet well understood.

Tolyltriazole (TTZ) primarily protects copper and brass and may also provide some protection for aluminum and solder.

Mercaptobenzothiazole (MBT) serves, along with benzotriazole and tolyltriazole, as a corrosion inhibitor for copper and brass. One aspect of the chemistry of mercaptobenzothiazole that should be recognized and understood is its sensitivity to light. Mercaptobenzothiazole undergoes an oxidative coupling reaction upon exposure to light to produce a compound that is insoluble in ethylene glycol.

Organic acids encompass a very large group of materials. Organic acids are typically added to the engine as the alkali or alkaline metal, aliphatic and/or aromatic, mono and/or dicarboxylic acid salts. The major purpose of these inhibitors is to replace traditional inhibitors such as silicate-silicone, nitrites, nitrate, phosphates, polyphosphates, amines, and borates.

Organic acid technology has shown long-term stability, good multimetal protection, and long-term protection of the cooling system.

Other Common Corrosion Inhibitors. Sodium molybdate's primary function is to protect ferrous metals, cast iron, and steel from corrosion. However, with the right combination of other inhibitors, sodium molybdate may also provide some protection for aluminum and solder.

Nitrate (as sodium or potassium salts) is a very good inhibitor for aluminum, usually added to a coolant to provide protection against pitting and crevice attack.

Nitrite (as sodium or potassium salts) is generally used as an inhibitor for cast iron to prevent cylinder liner pitting in heavy-duty engine applications. Concerns have been raised over the use of nitrite in conjunction with certain amines because of the potential of forming nitrosamines (a potential carcinogen). To avoid exposure to the consumer, nitrite has traditionally been used only in heavy-duty fleet coolant applications.

Antifoam is added to the coolant to control (minimize the amount and speed up the break time) the foam formed when the coolant is mixed with water. Failure to add it can lead to foaming problems when the customer installs the coolant in the car.

Dyes are added to the coolant to give it a characteristic color that allows the consumer to differentiate it from other automotive fluids (e.g., transmission fluid, windshield washer fluid). They come in a number of colors including yellow, green, red, blue, and orange and serve only to color the fluids; they have no corrosion-inhibiting properties.

Engine Coolant Testing

Certain chemical, physical, and performance properties of an engine coolant must be checked to ensure that it meets the specific requirements of the cooling system. ASTM, SAE, and vehicle manufacturers have developed standards and methods for this purpose (Table 1). ASTM standards are designed to check the physical and chemical performance of the engine coolant but are not designed to analyze the composition of the coolant.

These standards and test methods are used to control the quality and to ensure that a coolant complies with specified performance limits and to engineering specifications. Some methods may be used in test programs to determine the

changes to coolant after use in a vehicle. The absolute composition of the coolant concentrate can be obtained only by chemical analyses.

Specific tests are used to evaluate the effect of coolant on nonmetallic materials, such as radiators or heater hoses. Standard test methods are used to measure the hardness of elastomeric materials and determine changes in material (e.g., swelling, hardness, tensile strength, weight change) after exposure to coolant solutions under stressed conditions.

In the past, the corrosion of metals in the cooling system has received more attention than the degradation of nonmetals. Most tests look at corrosion of metal coupons that have been exposed to control test conditions.

The coolant performance tests can be divided into three categories:

Laboratory tests

- Physical properties tests
- Glassware corrosion test
- Foam tests
- Electrochemical tests
- Simulated service tests
- Heat rejection tests
- Stability tests

Special tests

- Pump cavitation tests
- Aluminum transport tests
- Engine dynamometer tests
- Compatibility tests

Field service tests

- Fleet proving ground tests
- Controlled vehicle fleet tests

Automotive, Light-Duty versus Heavy-Duty Antifreeze/Coolant

It is helpful to describe the differences between light-duty automotive and heavy-duty diesel engine coolants. Diesel engines are similar to gasoline engines in many ways. Both are internal combustion engines and most versions use a four-stroke cycle, but there are fundamental differences that are responsible for the development of different coolant formulations for each application.

Table 1 ASTM standard and test methods to determine physical, chemical, and performance properties of engine coolant concentrate

ASTM designation	Title
D 1119	Ash content of engine antifreezes, antirusts, and coolants
D 1120	Boiling point of engine coolants
D 1121	Reserve alkalinity of engine antifreezes, antirusts, and coolants
D 1122	Specific gravity of engine antifreezes by the hydrometer
D 1123	Water in engine coolant concentrate by Karl Fisher
D 1177/D 6660	Freezing point of aqueous engine coolant solution
D 1287	pH of engine antifreeze, antirusts, and coolants
D 1881	Foaming tendencies of engine coolants in glassware
D 1882	Effect of cooling system chemical solutions on organic finishes for automotive vehicles
D 3634	Trace chloride ion in engine antifreeze/coolants

The need for unique coolant chemistries is a function of the system operational design, the demands made upon the system by these conditions, and the typical cooling system maintenance program. Table 2 contrasts differences between automobile and heavy-duty diesel service. The expected life to overhaul for a heavy-duty engine is four to five times that of an automobile gasoline engine, despite the fact that the load factor is over twice as much and the gross vehicle weight per horsepower is five to eight times as high. For the diesel to work over twice as hard and still last four times as long, it is essential that the cooling system is well designed and maintained, filled with a quality, fully formulated heavy-duty coolant and periodically supplemented with supplement coolant additive or inhibitor extending packages (extender).

On the other hand, new gasoline engines use more lightweight metals (aluminum alloys and magnesium) as compared with diesel engines, which use cast iron and steel. Aluminum and cast iron require different inhibitor packages for protection against corrosion.

In addition to differences in design and cooling system conditions, use of heavy-duty coolant in automotive application is restricted by toxicity of some chemicals that are required to be used in heavy-duty vehicles. For example, the nitrite required in coolant formulation to protect replaceable or wet liners in wet sleeve heavy-duty engine cylinders might produce a nitrosoamine that is considered a carcinogenic agent and could be harmful.

For these reasons, it is recommended that automotive coolant be used in automotive and

light-duty applications, and fully formulated heavy-duty coolant be used in heavy-duty vehicles powered by diesel engines.

Automotive Proving Ground Corrosion Testing

Mats Ström, Volvo Car Corporation

COMPLETE VEHICLE ACCELERATED CORROSION TESTING as performed on the proving ground is a "mandatory" testing tool among vehicle manufacturers around the globe. It serves to verify the total quality of the corrosion protection of new models close to the start of production. This activity encompasses cars, sport utility vehicles (SUVs), trucks, and other commercial vehicles. In the automotive industry, complete vehicle testing is often regarded as an acceptable substitute for real service exposure, with the drawbacks of high cost and long lead time. It serves as a decision-making tool for issues ranging from a cost cut of cents per unit, to million-dollar investment issues. The test shall reproduce potential upcoming customer issues to the right proportions in a fraction of the time it takes outdoors. The determined failure modes should preferably be unambiguous and well documented, to let a nonexpert be able to evaluate and report the test outcome.

Apart from presenting and discussing the typical element of complete vehicle corrosion testing, an aim of this article is to create some awareness of the difficulty in applying reliable corrosion tests for everything at once and how this difficulty can be handled. A spectrum of physical, chemical, and electrochemical mechanisms are involved in a single atmospheric corrosion case. It is a challenge to simulate such a complex event to proceed in the similar manner in a typical 25-fold increase in rate, at which an accelerated test is expected to deliver reliable results. Taking an entire vehicle into account, one has to multiply this achievement for dozens of combinations of coatings, metallic materials, and designs, with the final goal of a balanced test outcome. To accomplish this within the same test regime, defined by a limited number of accelerating tools, is a formidable task that will at best, result in a reasonable compromise. This suggests that the test results should be treated as risk indicators that have to be assessed and weighed, rather than as precise predictions. Considered in this article is the extent that the high expectations can be met and the alternative evaluation routes at hand when

the lack of realistic results becomes too obvious. A number of practical examples regarding both corrosion cases and test equipment are discussed.

When To Use Complete Vehicle Testing

The primary value of complete vehicle testing is the evaluation of how technical solutions function in interaction with their specific vehicle environments, for example, considering exposure to wear from road grit, dirt, and salt load, elevated temperatures, and mechanical effects such as chafing and fretting.

The second value of a complete vehicle test is the ability to verify everything in one comprehensive test. Regarding new models to be launched, complete vehicle testing is preferably used when the quality of a test object on most levels has reached a productionlike status. The test is then used to verify and finalize the performance of most components and systems. The results may indicate the need for upgrades as well as suggest product rationalizations.

For models already in production, complete vehicle testing offers the opportunity to ensure that all parts are produced according to specifications. All production processes tend to drift with time. When implemented, product rationalizations have a tendency to result in inadvertent changes to other attributes than the intended ones. The very long warranty commitments offered on body perforations and the potential for causing future associated out-of-control costs is a strong driver to run more corrosion tests of products already in production.

Proving ground testing offers the most convenient way of comprehensive comparisons of quality outcome when vehicle manufacturers produce the same models in more than one plant. However, when only one or a few units are tested, it is unlikely to detect issues that come and go depending on stochastic or drifting variations in the manufacturing processes.

When Complete Vehicle Testing is Less Than Adequate

In spite of good intentions to detect and counteract issues at an early stage in a product program, it is of limited value to test very early prototypes because:

- Test objects lack, to a large extent, the detailed relevance regarding finishes and geometries that often are key variables in their corrosion performances. They do not represent the outcome from the actual production equipment.
- A significant time of the product program has elapsed before test results are reported and a wide span of changes has already affected the model. Because of this, negative test results are easily disregarded and decisions postponed, even in cases when actions would have been called for.
- Early prototypes are very expensive test objects.

Real-World Conditions the Tests are Aimed to Represent

The automotive corrosive environment is formed by the sum of a very large number of stochastic events on a time scale ranging from hours up to the time scale represented by averaged climate condition for a given global location (Ref 1). Humidity and its variation are key variables for corrosion propagation. Prevailing high humidities are typical for northern locations with maritime influence in winter season, exemplified by the Canadian east coast and the northwest areas of Europe, but also around the North American Great Lakes region. To generate high corrosive conditions that become a concern for vehicles, contaminants that promote corrosion have to be added. The winter-time use of deicing salts in cold and temperate areas is a major seasonal corrosion contributor in this context. Airborne saline load from the sea is another source, affecting many coastal areas. Subtropical sites where both high humidity and

temperature boost the corrosive effect of such a salt deposition are the worst of this kind. A third corrosive source is gaseous pollutants, especially sulfur dioxide, which still is a factor to consider in so-called emerging markets.

The salt type most widely used for wintertime deicing in the cold markets is sodium chloride. Some calcium chloride is often added to improve wet sticking to the roads (North America). In areas frequently affected by temperatures far below freezing, calcium chloride has found extensive use, but seems to have been gradually replaced by magnesium chloride in recent years. The use of calcium chloride for dust control of rural roads can also be mentioned in this context.

The salt load on a vehicle over time varies from saturated conditions to infinite dilution. The concentration of salt on the road will be dependent on the degree of drying or dilution, and the salt concentration of the wet films on the vehicle will be determined by the relative humidity. Temperature increase is often associated with rainfall, and "pure" water road splash will sometimes wash away salt, which limits the time with prevailing high salt loads at high outdoor temperatures. This goes for well-exposed areas not affected by established corrosion. In pockets and semi-open cavities, wash-off will seldom occur, if at all. Here, road dirt and soluble salts slowly form accretions by airborne transport. These areas often pose the worst corrosion risk on a vehicle. In established rust on mild steel, chloride ions act as a dissolution catalyst deep down at the rust/steel interface, and the corrosion process needs only infrequent and low-level wetting to continue almost year round. To the basic environmental corrosion factors is then added the complexities of how the vehicle is used by the customer in terms of:

- Road surfaces and the associated mechanical impact on vehicle components, including abrasive wear from stones and grits picked up and released from the tires
- Exposure to dirt and frequency and type of car washing
- Different driving modes often associated with local market conditions, which may cause high heat loads on one extreme and insufficient warming up on the other
- The way and frequency with which different vehicle systems are operated by the customer, for example, door locks and hand brake

In a representative accelerated test, these factors must be compressed into a standardized, comprehensible scheme of recurring events, suitable to run on durability tracks at a proving ground, combined with forced climatic conditions in a static chamber exposure.

Elements of a Complete Vehicle Corrosion Test

Proving ground corrosion tests typically consist of a repeated cycle of elements, where the four main test blocks are: (1) a driving sequence

on various proving ground tracks, (2) exposing the vehicle in one or more ways to road deicing salt(s), (3) static exposure to forced climatic conditions, and (4) additional elements such as operating the mechanical systems of the vehicle, car washes, and so forth. Based on the content of about 10 car manufacturer's complete vehicle corrosion tests (Ref 2), the following representative test conditions can be identified:

Test duration varies from 10 weeks to more than 20 weeks. Depending on test length and, sometimes, corrosion type, the test is interpreted to correspond to a service in the field ranging from 3 to 10 years in a corrosive reference market.

Use of Tracks. The common procedure is to have the vehicle running on tracks according to a specified sequence of events during workdays. This takes a few hours, depending on the brand-specific content. Otherwise, the vehicle is exposed in a climatized garage for most of the time. The durability tracks at the proving ground usually have their core function in vehicle programs for pure mechanical endurance testing. For corrosion testing, the tracks allow field-representative effects of twisting, vibrations, chafing, and fretting to interact with the effects of the corrosive environment. Among the elements of the tracks are cobblestone pavings or Belgian blocks, washboards with various wavelengths, potholes, and railroad crossings. Handling roads (curves, hills) accentuate side forces and chassis dynamics. The SUVs and heavy-duty vehicles have more demanding rough roads included in the driving schemes.

Another regular element of driving is mileage accumulation, usually performed on the high-speed track. Typical speeds range from 80 to 130 km/h (50 to 80 mph). The purpose is general aging by driving, drying up of wet films of salt and other contaminants, and in some tests the generation of high peak temperatures in subsequent parking.

A mandatory testing component is driving on a gravel road in order to generate self-induced abrasive wear from grit picked up and released from the tires of the test vehicle. Grit size used in these tests usually ranges from 4 to 10 mm (0.16 to 0.4 in.) in diameter. The road surface under the gravel varies from asphalt to dirt beds in different tests and the depth of the gravel from scattered to thick beds. Some tests also have a follower procedure with a vehicle running ahead of the test object in order to generate stone pecking on the test vehicle, usually implemented at the test start.

Dust tracks and mud pits are used to build up dirt accumulation from high-speed and low-speed conditions, respectively.

There are still some vehicle manufacturers that do not test exclusively under proving ground conditions, that is, road elements of the tests are simulated in static rigs or performed on public roads.

Three methods are used to contaminate the vehicles with salt solution:

- Highway simulating splash/spray at medium speed (60 to 90 km/h, or 35 to 55 mph). The length of these passages range from 50 to 400 m (165 to 1310 ft), sometimes combined with washboard road disturbances (Fig. 1).
- Low-speed passages through troughs with typically 50 to 80 mm (2 to 3 in.) depth of saltwater
- Exposure to spray or salt fog solution on the static vehicle

Sodium chloride dominates as the dissolved corrosive agent. In some tests, calcium chloride and other contaminants are added. The concentration of salt in solution has typically been 3 to 5 wt%, but lower concentrations at the 0.5 to 1% level are found in more recently upgraded test procedures. No vehicle manufacturer, to the author's knowledge, applies gaseous corrosive agents such as sulfur dioxide in complete vehicle test application.

The major part of corrosion takes place under immobile conditions in special garages at elevated temperature and humidity. The exposure to forced climatic conditions is often programmable with respect to temperature and humidity cycling (Fig. 2, 3). The percentage of a full test the vehicle spends under climatized conditions ranges from 30 to 85%. It is important to note that the lower end represents very high humidity conditions only, whereas extensive periods of semidry conditions are included in the climate programs in the latter case.

About half of the vehicle manufacturers use some kind of cold room to reach vehicle temperatures far below freezing. In one known case, this was combined with stone-pecking exposure. Rig testing that combines climatic exposure with mechanical loads is seldom used. One case of salt spraying on the static test vehicle in wind-tunnel-like conditions is reported.

Evaluation of Test Results

Corrosion inspections during the test are usually conducted weekly or biweekly. The final inspection after test completion often takes substantial time. In many cases it comprises a total dismantling of the vehicle, including opening of joints and cavities in the sheet metal structure. Detailed analysis is usually performed and reported in-house, but some companies let main system suppliers take care of substantial parts of the test evaluation.

Corrosion requirements are classed into either of two major attributes: appearance and function. Requirements on appearance can stretch from what the customer finds on the vehicle in the retail showroom to penetrative corrosion in closures after several years. In terms of test inspections, this corresponds to results at a fraction of the test time and at the completed test, respectively. The latter may even involve projections extending far beyond the final result. Long anti-perforation warranties on body and

Fig. 1 Proving ground highway simulating splash/spray during high wintertime conditions with deicing salt use. Note the shallow splash groves in the highway.

Fig. 2 Garaging of a test car in a proving ground humidity chamber after a daily test track driving sequence

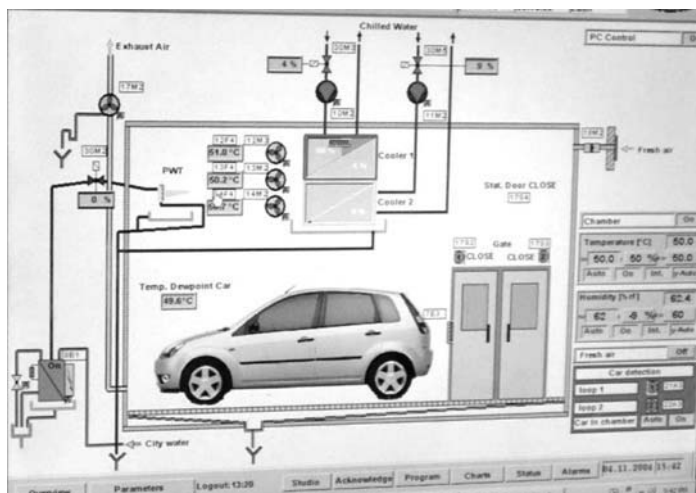

Fig. 3 Computer-controlled monitoring of corrosive conditions in a modern programmable complete vehicle humidity chamber

closures are strong drivers for such extrapolations.

Requirements on function usually address mechanical or electrical functionality when affected by corrosion, ranging from poor serviceability to structural disintegration. A major part of these demands are of the full-service-life type.

There are two approaches to proving ground corrosion tests for systems that are expected to function throughout the full vehicle service life:

- **Full-service-life test:** Test is run for at least 20 weeks, interpreted to directly represent full service life, meant to correspond to at least 10 years-in-service (YiS). In its most simplified approach, components that pass the test without actual breakdown are checked off as okay without further analysis. Systems with lower requirements are then checked

for function at specified times during the exposure.

- **Projection:** Tests are run for typically 12 weeks, often interpreted to correspond to 6 YiS in a certain corrosive reference market. Damage to parts expected to function the full vehicle service life is extrapolated to their critical time regarding required customer YiS. The parts are then assessed as to whether they are likely to pass the requirement or not.

In both approaches there are different views on how to design the test, all from pushing very hard to acting more restrictively and selectively on the parameter settings.

Simulation and Acceleration

Which test is the most severe? How many years does the test represent? Can one test more

quickly? These are common questions from the engineering community, which typically is not aware of the complications discussed in this section.

As already indicated in the introduction, for a complex product it is not possible to acquire such a balanced outcome from an accelerated test that it can be unambiguously and clearly translated to “x” years in customer service. Increased acceleration of a test usually leads to decreased correlation with the field tests (Ref 3, 4) for the same reason as any remodeling of reality inevitably introduces scaling errors. With the good intention of designing a tough and quick test, conditions for creating nonrelevant phenomena are introduced (Ref 3, 5). If results generated in such tests are not modulated through field references, misleading conclusions can be converted into automotive manufacturing practice.

Effects of Humidity and Salt. The exposure to humidity, wetness, and associated dissolved aggressive ions is the standard cause of corrosion on automotive products. However, too much of either wetness or salt load in a test may counteract its intended purpose.

Some corrosion mechanisms require that the electrolytic activity be somewhat restricted, otherwise their typical mode will hardly manifest at all. A typical example is filiform corrosion underpaint “creepage” on aluminum (Ref 6). Another example is galvanic corrosion localized to a bimetallic interface, and especially under crevice conditions. Under realistic conditions, deep pitting in the less noble metal may lead to localized penetration at the bimetallic contact. A high salt load in a test may not be able to mimic this behavior. The overall corrosion rate will be high, but the associated high electrolytic activity that leads to the anodic reaction becomes “smeared out” over a large surface. Under these conditions, the local maximum penetration depth will in effect be smaller than in a case with a lower electrolytic activity.

Zinc coatings will dissolve very actively when affected by long exposure to wetness and/or high salt loads, resulting in ample formation of white corrosion products that generally differs from those formed in the field. Painted or passivated zinc-coated steels become “prematurely” rusty, especially at sheet metal edges. The reason is that the basic carbonates and basic chloride of zinc are outside their thermodynamic stability ranges and cannot act as passive films. Instead, a self-promoting active mode with zinc oxide formation will dominate (Ref 7, 8).

With high salt loads, the rust formed on poorly treated steel/cast iron components develops into test-specific morphologies (Fig. 4, 5). Openly exposed surfaces quickly become heavily rusted since steel/iron readily responds to a wide range of nominally accelerated conditions, whereas the same material in confined mode is easily made nonreactive by excessive electrolytic activity (Fig. 6). Motor vehicles in the field display more selective rust locations and have almost exclusively rust penetrations located in or at crevices such as spot-weld overlaps and hem flanges. Unfortunately, crevice corrosion seems to be the most difficult type to accelerate and to keep to scale with other corrosion types. Therefore, in accelerated testing under harsh conditions, rust penetrations, if occurring, are located in open and worn positions rather than in crevices.

A special manifestation of the problem described previously is often encountered in standard scribe tests for evaluation of adhesion/corrosion properties of paint systems applied on a steel base (Fig. 4). Already a moderately aggressive combination of salt and wetness causes inhibition of paint creepage if sufficient cyclic drying is not introduced in the test procedure.

Figure 7 illustrates the acceleration dilemma, showing typical corrosion rate responses for steel and zinc as a function of “nominal corrosivity” (qualitative, collective term for degree

of humidity exposure/time of wetness, extent of drying, and load of deliquescent salts). In this simple representation there is no accelerating condition to be found that results in balanced scaling between the presented corrosion modes. To make the problem worse, there seem to be corrosion mechanisms that require a high and extended wet load in order to be initiated. Based on field experience, the hydrolysis of polymers and their adhesion interfaces to metals are likely to be precursors to the onset of corrosion.

Effects of High Test Temperatures. Raising the temperature is the standard acceleration tool, as this increases the probability to exceed activation barriers for single chemical steps (Arrhenius equation). However, activation energies and temperature dependencies differ for different types of reactions and hence their temperature dependence. Furthermore, a corrosion process usually comprises a number of parallel and consecutive subreactions where feedback is common, and a temperature increase may facilitate passivation or activate corrosion. There is also a thermodynamic displacement factor that affects the stability ranges of different participating species when changing the temperature. One example is the Schikorr reaction ($3 \text{ Fe(OH)}_2 \rightarrow \text{Fe}_3\text{O}_4 + 2\text{H}_2\text{O} + \text{H}_2$) (Ref 9), which is barely detectable below 50°C (120°F) but may produce hydrogen in the corrosion cells at the steel interface at higher temperatures (the probable cause of the blisters in Fig. 5).

Zinc readily forms protective layers of basic salts of carbonate and chloride in the high-temperature regime if there is access of atmospheric carbon dioxide (CO_2), which is the key passivation promoter (Ref 7). This is the probable cause of the lack of positive temperature dependence for the atmospheric corrosion of zinc found under moderate salt exposures (Ref 8). However, long periods of wetness and high loads of deposited salt counteract the formation of protective films and promotes

continuing high activity, as discussed previously. Hence, zinc becomes sensitive to the testing conditions, and consequently the results become sluggish. An example is zinc corrosion associated with interfacial undermining of paints and sealants, which is rather frequently encountered on automobiles in corrosive regions. This mode of corrosion is difficult to simulate in a high-temperature regime unless high loads of salt are used to counteract the enhanced tendency for passivation.

Corrosion Effects of Driving Events. The durability test track driving effects, such as twisting, shear forces, and vibrations, have limited impact on most corrosion results. However, when mechanical forces trigger corrosion, the alarm bell should sound, since many findings such as this have shown to reflect highly significant customer quality issues. Examples are wear on paint from mounted components or between sheet metal parts. Electrical cables and wire harnesses can be routed so that they inadvertently rub on distribution pipes. Fine particles from dust roads can contribute to fretting wear between components, which are not sufficiently fixed to each other, eventually resulting in issues affecting either appearance or function. On the other hand, the mechanical impact of stone pecking from rough road conditions can result in exaggerated damages. Most proving ground tests have a constant interaction between a corrosive environment and gravel roads, which causes many painted steel components to become quickly stripped of paint and exposed to corrosive conditions sooner than what is representative for most customer vehicles.

Compromising Corrosive Conditions. In spite of identified drawbacks, an accelerating parameter set characterized by a high exposure temperature combined with a low salt load results in a better balance for most corrosion types than vice versa (Ref 3). However, using high-humidity exposure conditions at temperatures above 50°C (120°F) seems dubious, due to thermodynamic and kinetic considerations. The relative humidity conditions should be cycled between wet and semidry conditions, where slow drying in the intermediate humidity range seems to yield the most fieldlike results. The design of the humidity cycle has dramatic

Fig. 4 Monitoring of underpaint “creepage” from scribe line(s) in the same automotive paint system on cold-rolled steel test panels. Panels 1–3: 12 week results from proving ground tests with decreased nominal corrosion load (panel No. 1 most severe) showing “blocked,” “semiblocked,” and “open” creepage modes, respectively. Panel 4: typical result from 3 year on-vehicle exposure in corrosive panel position/environment. Panel 5: 12 week laboratory test showing all three creepage modes on the same panel due to different salt accumulation caused by scribe orientation and panel inclination

Fig. 5 Rust morphology under different degrees of corrosivity. Upper panels show gas blisters in the diffusion-tight rust. Lower panels show a more open rust morphology at nominally the same average corrosion depth

Fig. 6 Monitoring of crevice corrosion (confined mode) in electrocoated and primed mild steel sheet panels. A 25 mm (1 in.) circular portion of exposed metal (lid removed) is shown. (a) shallow 6 week attack and magnetite slurry after nominally hard exposure conditions resulting in almost constant wetness. (b) 2 year on-vehicle exposure

influence on the corrosion results, especially on the relation between that of open exposure and confined mode.

Plain sodium chloride solution is found to be an appropriate corrosion promoter and is used in most test procedures. The possible benefits of more complex blends have not been sufficiently demonstrated. The strong corrosive effect of the sodium ion, which has not been recognized in the past (Ref 10), is one good reason for taking this position. Much larger effects are found both from the salt load level and from how the humidity exposure is designed.

Aspects of Test Equipment and Track Conditions

The climate chamber (garage) is where most of the actual corrosion takes place even in the proving ground case. There are some very important factors to consider in order to have defined conditions. As described in this section, these include the level of relative humidity (RH), exposure to road salt, and particulate contaminations.

High humidity exposure at saturated conditions (100% RH) is rather widely used in cyclic corrosion tests utilizing deliquescent salt(s). However, equilibrium salt concentrations are not defined at 100% RH. Any salt film, irrespective of amount or type, will dilute infinitely as water is gradually absorbed on the exterior of the test object. Runoff will inevitably result until, eventually, there is practically no salt load left on the surfaces. This may seem relevant enough, since undeniably this occurs under real field conditions. However, there is an associated reproducibility (and perhaps a repeatability) problem. The dilution rate is dependent on the mass transport of water to the surfaces of the test object, and accordingly to the speed of the air (steam) flow in the climate chamber. The

dilution rate on a vehicle will not be uniform even within the same chamber, and of course, much less so for different types of chambers (and vehicles). Completely unacceptable is a tolerance span of the type "95 to 100% RH" as seen in some test specifications, which means that quite different climatic conditions are accepted within the same test specification.

A related phenomenon is when a cool vehicle is parked in the chamber after driving on the tracks. Outdoor conditions are often below freezing in temperate areas, whereas the dew point in the test chamber may be close to 50 °C (120 °F). Under such a dramatic transition the vehicle immediately becomes soaked, and run-off of the salt film will quickly occur, which is probably not intended. A remedy is to have a program that restarts each time the test vehicle is garaged and then starts with a controlled ramping up to set temperature before the humidification is initiated.

Dilution of the salt film under climatic exposure can, however, be beneficial in one important aspect. It counteracts the previously discussed negative effects of very high salt loads used in many tests.

Exposure to Road Salt and Conditions for a Run-Through Spray/Splash Section. The single most important factor that decides what will corrode and to what extent the corrosion will proceed is how the salt solution is distributed over the vehicle. In areas using road-deicing agents on the highways in wintertime, the vehicle will typically be exposed to salty aerosols for miles. Spray and splashes will come from passing vehicles, but the effect on the undercarriage is mainly self-induced, predominantly by high-speed driving through shallow grooves on normal paving. On the proving ground, these conditions are best reproduced in a passage with spraying and splash conditions. However, there are some aspects to consider when the described highway elements are translated into a test section. Spraying nozzles must be able to generate a representative pattern and spectrum of droplet sizes, to represent both structural ingress and sufficient exterior wetting. A proving-ground passage must necessarily be very short compared to any real highway condition, but must generate sufficient speed, and both needs are difficult to satisfy. A scaling error that very easily occurs is the gradual buildup of salt depositions in positions "semiaccessible" to the spray, or affected by secondary runs. In highway conditions these positions will be rinsed by the same kind of road spray, containing only rainwater during most of the year. A remedy to this unbalance is either to decrease salt concentration or to alternate with pure water in the spray passage.

The main alternatives to a spray/splash passage—static spraying or ploughing through a trench of saltwater at low speed—will bias some vehicle areas but leave others unaffected. With these less field-representative salt applications there is an obvious risk that the resulting corrosion will lack correlation with what is found in the field.

Particulate Contaminations. Another problem is the restricted ability to generate fieldlike depositions of mud and dirt in some "semi-accessible" positions. Dirt accumulations can have considerable long-term impact on various surface treatments. The dirt accumulation on most field vehicles is a slow but continuous process where road particles (ranging from mm to μm) from all kind of pavings settles in aerodynamic "backflow" areas. In an accelerated mode, it is difficult to keep up with this process even if passing dust-generating test sections. Frequent underbody splashes may also counteract dirt accumulation. The use of slow driving in so-called mud pits will generate dirt accumulations, but is less representative of the accumulations found on most customer vehicles.

Monitoring the Corrosivity

A traditional way of monitoring the corrosivity of proving ground corrosion environments is to assemble a number of standardized mild steel plates in a standard position and to evaluate them on a number of occasions during or after the corrosion test, usually as metal loss by gravimetry after removing the corrosion products. Ironically, mild steel in open corrosion mode shows a high and surprisingly stable corrosion rate under a very broad range of nominally differing corrosive conditions (Fig. 7). For reasons discussed previously, zinc provides a more sensitive choice in this respect. A more sophisticated way is to monitor the corrosion environment itself in field and proving grounds, respectively, which is treated in Ref 11 to 13.

An Evaluation Strategy that Complies with Constraints in Accelerated Testing

The major advantage of the full-service-life test approach is that it offers a straightforward evaluation and that the results are easily comprehended when communicated to the engineering staff and its management. Both these factors also save manpower and do not require expertise involvement. On the other hand, the obvious drawbacks can be summarized:

- **Long test:** Within the time constraints of contemporary new automotive brand model programs there is no time for long-term testing. Waiting for a reasonably relevant prototype to be tested means that start of production will have passed when the test results are at hand. The inevitable imbalance in acceleration of different corrosion types results in gradual loss of correlation to field as the test progresses, rather than in otherwise undetected relevant failures emerging with time.
- **Severe test:** Running a more severe test with the aim to cover full-service-life conditions will seldom reach the intended target. More individual issues will be found, but a considerable share of those will be test artifacts

Fig. 7 Typical corrosion rate response (YiS, years in service) for steel and zinc during a 12 week test as a function of increased "nominal corrosivity" (a qualitative term for degree of humidity exposure/time of wetness, extent of drying, and salt load)

seldom (or never) encountered in customer use. However, the test protocol calls for cost-driving actions. Eventually this may take another turn, and the test outcome may be questioned as a whole, including the relevant issues.

- **Evaluation:** From a statistical standpoint, the least improvement for a single (or few) sample test is to consider not only explicit failures. Damages that represent obvious risks (e.g., base metal corrosion to considerable depth) must also be treated as deviations since they indicate that a significant fraction of the customer fleet is likely to violate the quality requirement unless countermeasures are taken.

This brings to consideration the alternative, the comparatively shorter “projection” type of test. Figure 8 illustrates how this procedure is aimed to function at its most favorable conditions. To use and interpret comparatively short tests suiting the product programs requires support from corrosion experience originating from the company’s technical organization. Individuals with experience must be at hand and responsible for collecting data and building knowledge and be able to correctly interpret indications of corrosion in a short test. With the often lean staffing of many base organizations, this may be problematic.

In order to limit the need for expertise involvement on every issue, the following strategy can be implemented:

- Determine test acceleration factors for typical, recurring classes of material/designs

Fig. 8 Example of how functional requirements on components (involving a specific corrosion mode) are verified by formalized proving ground (PG) test outcome criteria (YiS, years in service). The most benign case for assessing long-term requirements is a “short” test based on previous field survey results.

based on gathered knowledge from field surveys, on-vehicle testing, quality issues, warranty databases, etc.

- Create real-time scales (rulers) of corrosive degeneration, backed up by photos, physical components, and so forth. Define where on the scale a given test delivers. Designed correlation test panels, exposed both in field and tests can facilitate this process.
- Extrapolate the test result for a certain corrosion type/component to the time specified by the service-life requirement (linearly often sufficient if data are lacking).
- Formalize and document such a process; that is, there should be system requirements that explicitly state the acceptable outcome of the test, based on the projection procedure (numbered circles in Fig. 8).
- In such a document, be very restrictive in the acceptance of corrosion modes that are known to be associated with a lack of robustness, such as adhesion failures.

New materials, surface treatments, or their new combinations/implementations should first have been investigated in laboratory testing by designed experiments in order to understand their operating limits and degree of robustness. Verifying solely on a test vehicle late in a product program will not deliver the sufficient degree of quality assurance. The incorporation of new knowledge and field experiences must be an ongoing process resulting in requirements and test conditions being revised and updated on a regular basis.

Conclusions

The aim of this article has been to create some awareness of the difficulty in applying reliable corrosion tests for all corrosion-sensitive automotive systems at once. To put it frankly, a proving ground test only partly proves things. A main message is: do not push too hard or kinetic backlashes may be misleading, for example, steel corrosion becomes diffusion-blocked by amorphous rust and crevice corrosion becomes impeded by constant wetness. Complexity and strong feedback mechanisms make sophisticated predictability and ranking of different corrosion protection systems impractical under accelerated conditions. The climatic accelerators must be applied with caution. The exposure temperature is preferably used as the main accelerator, although 50 °C (120 °F) seems an appropriate upper limit. Frequent and long drying cycles at intermediate relative humidities followed by rewetting is recommended. Avoid excessive salt loads, both regarding frequency and concentration. Try to apply the salt load as fieldlike as possible in order to reach good results. Increase the probability to discover potentially nonrobust behavior by widening the “spectrum” of the test, especially regarding the humidity conditions.

Even so, a well-designed test of 10 to 12 weeks duration cannot be driven so hard that extra-

polations of the test results can be avoided for vehicle systems that are expected to function throughout the whole service life, or a test must be very long (>20 weeks). For such projections, use a formalized and documented procedure based on field data, which explicitly states the acceptable outcome of the test for a certain corrosion mode.

Finally, there is somewhat of a contradiction in the whole concept outlined previously. By the time one has gathered sufficient knowledge to perform good testing, so much will be known about what is tested that testing will be less important. At this stage, one will be able to specify the most cost-effective solutions at the early design phase of a product program, and the complete vehicle test will be the final sign-off verification tool. In conclusion, there is no way to escape the constant need of “one foot in the field” for highprecision quality assurance.

Corrosion of Aluminum Components in the Automotive Industry

Greg Courval, Alcan International Limited

ALUMINUM COMPONENTS and assembled structures generally show very high resistance to corrosive environments when properly designed and manufactured with appropriate alloys. This article provides an overview of the principle forms of corrosion that can occur on automotive aluminum components and offers general guidelines on how best to avoid these situations. To this end, it is more informative to examine the mechanisms by which corrosion can occur, rather than to focus on specific components. This article does not cover the fundamental principles of aluminum corrosion as this can be found in other parts of the Handbook. In addition, it is generally known that specific corrosion issues have to be examined on a case-by-case basis. There are many unique features of any particular component or assembled module that dictate the methods that can be used to provide good corrosion protection. The guidelines offered are therefore of a general nature, and great care to detail and field experience must be applied to any specific problem.

Only the most common forms of aluminum corrosion are covered:

- Stress-induced corrosion
- Cosmetic corrosion
- Crevice corrosion
- Galvanic corrosion

In addition, pitting and intergranular corrosion can occur on bare aluminum components such as heat exchangers or suspension parts. This type of corrosion may lead to a deterioration in surface appearance, but in some cases also affects the service life of the part. Corrosion fatigue can be an issue affecting dynamically loaded aluminum structures, and care must be taken to avoid sharp notches and fine surface cracks. The best way to avoid corrosion fatigue is through proper design and the use of suitable protective coatings. A good review of pitting, intergranular, and corrosion fatigue is available in the *Aluminium Automotive Manual* (Ref 1).

Stress-Induced Corrosion

Aluminum Association (AA) 5xxx series alloys and certain AlMg casting alloys, commonly used for structural components, with magnesium content above about 3% can be susceptible to stress-corrosion cracking after extended exposure to elevated temperatures. Some 2xxx, 7xxx, and 6xxx with high copper additions are also susceptible to stress-corrosion cracking, but these are generally not used in automotive applications. For this reason, the AA guidelines (Ref 2, 3) strongly recommend alloys with a maximum of 3% Mg for structural components in automotive applications, where exposure for long periods to temperatures in excess of about 75 °C (167 °F) occurs. When the use of AlMg alloys with higher magnesium content is desired, consultation with the material producer is recommended and their applicability must be evaluated in detail. The thermal exposure of the part during its lifetime should be known, and preferably a realistic, full component test should be performed. These guidelines are generally followed, and the author and colleagues are not aware of any in-service failures of components due to stress-corrosion cracking. For example, the Honda NSX (Ref 4), which has used 5182, a 4.5% Mg alloy in a number of structural components for almost 15 years, has no known record of field failures due to stress-corrosion cracking. Therefore, this issue is not covered any further in this article.

Cosmetic Corrosion

Cosmetic corrosion generally refers to paint performance of class "A" outer body panels. To fully understand and evaluate the reasons related to cosmetic corrosion issues, the performance of the complete original equipment manufacturer cleaning, phosphating (or alternative chemical pretreatment), and multilayer paint system must be taken into consideration, as well as the characteristics of the alloy and

its surface condition. A complete review of all these factors is well beyond the scope of this article. For a more detailed analysis, the reader is referred to the work underway on correlating lab tests of cosmetic corrosion with in-service performance (Ref 5). From general experience, it can be stated that, provided all the necessary coating system preparation and application precautions are taken, service performance of painted aluminum closures has been excellent.

With respect to the painting of individual components, surface preparation prior to paint application is absolutely critical in order to achieve optimum corrosion performance. This is particularly the case for components such as cast aluminum wheels.

Crevice Corrosion

Crevice corrosion on aluminum components can occur whenever moisture enters the crevice area between two adjoining surfaces, especially if salts are also present. Often, the two adjoining surfaces would be aluminum but, as is shown in some examples, one of the surfaces can also be of another material. It should be noted that once the corrosion starts, it can propagate intergranularly. Crevice corrosion is most critical for situations where the crevice is formed by two conducting materials with different electrochemical potentials leading to an additional galvanic effect. The next section covers galvanic corrosion.

Figure 1 shows an example of crevice corrosion underneath a carpet that covered aluminum steps on a vehicle. Moisture and salts had penetrated into the crevice under a fastener between the carpet and the aluminum surface. The carpet served as a reservoir for electrolyte. In order to rectify this situation, a sealant was applied over the entire area between the carpet and the step, forming a barrier to penetration of moisture and salts. This example was selected to demonstrate how the use of sealants can be

very effective in eliminating crevice corrosion issues.

In addition to the use of sealants, design of joints effectively eliminates the potential of crevice corrosion. In essence, components should be constructed in such a manner that entrapment areas for moisture, salts, and dirt are avoided as much as possible (Fig. 2). The joints are made to allow good drainage and prevent the buildup of poultices that can trap salts and moisture. More complete guidelines for the design of components to avoid or reduce corrosion issues can be found in the Aluminum Association literature (Ref 2) and in the article "Designing to Minimize Corrosion" in Volume 13A, *ASM Handbook*.

Consideration should also be given to allowing paint or other corrosion protective coatings access into crevice areas. This is particularly

Fig. 1 Crevice corrosion under a floor cover in the proximity of a fastener

Fig. 2 Design guidelines for corrosion prevention. The component is fabricated so that retention of moisture, salts, and dirt in crevice areas is avoided.

important whenever electrocoating techniques are applied. If a joint area is very tight, the paint cannot penetrate the crevice. However, a small gap between adjoining surfaces sufficient to allow access provides a barrier to corrosion activity. A large gap that would allow pooling of the paint beyond its recommended thickness should be avoided.

Another example of crevice corrosion is shown in Fig. 3. In this case, the rubber gasket around a bare aluminum windshield frame resulted in minor corrosion-related discoloration of the metal. Please note that the small hole in the middle of the component indicates the position of a screw and is not a result of any corrosive activity. Application of a sealant between the gasket and the aluminum or prior painting of the aluminum surface would have prevented corrosion from occurring. Whenever a sealant is used in any of these applications, it is important to ensure the sealant remains pliable. Sealants that dry out and crack allow access of moisture into crevice areas and can even accelerate the rate of crevice corrosion. The example shown in Fig. 3 crosses the boundary between crevice and galvanic corrosion in that rubber or other plastics containing carbon black can show galvanic corrosion in contact with aluminum. Selection of the proper grade and level of carbon black in the rubber must be considered to avoid this issue (Ref 6).

Another form of crevice corrosion originates from the use of certain foam materials occasionally used for sound-dampening purposes. Some of these foams can retain moisture and salts and may lead to corrosion if there is no barrier material between the foam and the aluminum component. It is best to avoid the use of such materials and select a product that does not act to retain moisture.

In summary, guidelines for the prevention of crevice corrosion effects include:

- Design of the component to allow good drainage and prevention of moisture, salt, and dirt retention in crevice areas is critical.
- Wherever possible, sufficient gaps should be left between components on a vehicle body to allow ingress of electrocoat primer into crevice areas.
- The use of paint and sealers between adjoining surfaces can be very helpful in preventing most crevice corrosion issues.

Fig. 3 Crevice corrosion under a windshield gasket

Galvanic Corrosion

Galvanic corrosion can occur whenever two dissimilar metals (or more generally electrically conductive materials) are in contact in the presence of an electrolyte. A common incidence of galvanic corrosion is caused by the use of steel fasteners. Often, the aluminum component is fastened to a steel component, which is then another source of galvanic action. The primary prevention method is the use of barrier materials to isolate steel from aluminum, thereby eliminating electrical contact. An example of such a system is shown in Fig. 4. The choice of the fastener protection material is critical. There are a number of sacrificial coatings that provide excellent protection against galvanic corrosion effects between aluminum and steel; most important are zinc powder and/or aluminum flake in an organic binder. Various grades are available, and detailed discussion with the manufacturer is required to be sure the coating meets the requirements for the specific application. It is also necessary to ensure the coating is properly applied, otherwise much of the protection could be lost prior to or during assembly. Other types of protective coatings on fasteners are also available, including aluminum and tin-plated layers. Stainless steel fasteners can be used without any protective coating, but it should be noted that their use does not necessarily prevent galvanic corrosion from occurring. Experience has shown that properly galvanized steel fasteners are very effective in providing excellent galvanic corrosion prevention.

The nonconductive barrier material between the steel and aluminum components may be a paint, sealer, or polymeric material such as a polyester tape. There is a wide choice of barrier materials, and consideration must be given to cost and ease of manufacture as well as the degree of corrosion prevention required based on the location of the joint. The requirement for a sealer to remain flexible and not to dry out or become brittle applies in this use as well. In any situation where moisture and salts can accumulate, additional sealant should be applied outside of the immediate joint area to isolate the seam as much as possible.

It is important to note, as shown in Fig. 4, that the barrier material should extend beyond the immediate contact area between the dissimilar

Fig. 4 Methods of sealing crevices between steel and aluminum surfaces

metals. A distance of about 10 to 20 mm (0.375 to 0.75 in.) is usually adequate. If the barrier material covers only the adjoining surfaces, electrolyte can form a bridge between the two metals and corrosion can occur.

Prepainting of the steel component prior to joining to the aluminum sections is often a very effective method of preventing galvanic corrosion. Again, consideration must be given to the overall requirements for manufacturing and cost.

Although most galvanic corrosion concerns are associated with steel-to-aluminum contact, other metals such as copper can also result in galvanic corrosion with aluminum if joints are not properly protected. One particular example is the use of copper grounding wire in contact with an aluminum structural component. An isolated joint between the copper and an aluminum wire, with the aluminum wire subsequently joined to the structural component has been proposed (Ref 6) as a means of avoiding these situations.

These measures provide excellent corrosion performance in service. However, there are alternative joining technologies such as adhesive

bonding to replace fasteners if concerns over galvanic corrosion remain.

In summary, these guidelines can help prevent galvanic and crevice corrosion of aluminum components:

- Avoid entrapment areas where moisture, salts, and poultices can accumulate in or near a galvanic couple. Sufficient space should be left between steel and aluminum components to allow electrocoat paint to enter the crevice and form a barrier between the dissimilar metals.
- Use properly protected fasteners and consider the material selected for the fastener. Primers, sealers, and other barrier materials should be applied appropriately to fasteners and the adjoining surfaces of a galvanic couple. The barrier material should extend beyond the immediate contact area of the joint.
- Use of prepainted components prior to assembly should be considered where possible. If applicable, also the use of alternative joining methods such as adhesive bonding should be considered.

Electric Rail Corrosion and Corrosion Control

Stuart Greenberger and Teresa Elliott, City of Portland, Oregon

ELECTRIC STREETCAR TROLLEYS AND LIGHT RAILS are once again popular, and their resurgence has a large impact on the city street—above and below ground. City streets are both traffic rights-of-ways and utility corridors. On downtown streets, electric rail transit shares the road with water, sewer, natural gas and fuel lines, electric power, communication, and traffic utilities. This article presents the fundamentals of stray-current corrosion caused by electric rail transit systems, electric rail system design for corrosion control, and the electric rail impacts to utilities that neighbor the transit system. Additional information can be found in the article “Stray-Current Corrosion” in Volume 13A.

Corrosion-control design elements for electric rail include substation spacing and grounding, track and track slab design, and construction acceptance criteria. The impacts of electric rail construction on underground utilities are discussed as direct physical interferences, maintenance access encroachments, stray-current effects, and utility relocation design considerations. Construction issues include construction funding, construction sequencing, and post-construction monitoring and maintenance by the transit agency and by the utilities.

Stray-Current Effects

Streetcar and light rail trains are powered by electric motors. Electric current flows from a direct current substation to the train through an overhead wire, and the current returns from the train to the substation through the rails. Because the earth acts as a parallel conductor to the rail, a portion of the current will return to the substation through the soil. This current returning through the soil is referred to as “stray current” because it follows a path other than the intended circuit. The engineering convention of electric-current flow from positive to negative, through metal conductors and the soil, is used throughout this article.

Stray currents cause electrolytic corrosion of both the transit system and neighboring utilities. The rail and rail fasteners corrode where

stray current leaves the rail and enters the soil. Stray-current flow in the earth is through a large, three-dimensional space, through both the soil and metallic underground utilities such as pipes and cables. The current follows multiple paths, which can be quite a maze as the current transfers from one underground structure to another. Corrosion will occur where the current leaves neighboring underground utility structures on its return route to the transit system.

Corrosion occurs at those locations where the current leaves a structure because, in the transfer of current across a metal/soil interface, there is electron transfer and associated electrochemical reactions. Metal atoms lose electrons and go into solution. The amount of metal loss is proportional to the total amount of direct current. Therefore, metal loss (corrosion) is related to the magnitude and the duration of the current. Metal loss from current discharge is quantified in Faraday’s law of electrolysis:

$$m = \frac{Ita}{nF} \quad (\text{Eq 1})$$

where m is the metal loss (lb), I is the current (A, or 1 C/s), t is the time (s), a is the atomic weight (lb), n is the charge equivalents exchanged, and F is Faraday’s constant (96,500 C/charge equivalent).

The metal losses that result from one ampere per year of stray current for some common construction metals are 6.5 lb (2.95 kg) for aluminum, 20 lb (9.1 kg) for steel or iron, 24.5 lb (11.1 kg) for zinc, 45 lb (20.4 kg) for copper, and 74.5 lb (33.8 kg) for lead. This metal loss can also be expressed as a surface corrosion or penetration rate in mils per year by considering the mass loss per unit area and the density of the material. This proportionality is shown in Eq 2, with the conversion factor of 12,000 mils/ft:

$$p = \frac{12,000ir}{d} \quad (\text{Eq 2})$$

where p is the corrosion (penetration) rate (mils/yr), i is the current density (A/ft²), r is the metal loss rate (lb/A-yr), and d is the metal density (lb/ft³).

The corrosion rate of steel and iron is 488 mils/yr (12.4 mm/yr) at a current density of 1 A/ft² (10.8 A/m²) or 0.5 mils/yr (12.7 μm/yr) at a current density of 1 mA/ft² (10.8 mA/m²).

Estimating the corrosion effects on a structure requires engineering judgment. For example, in the case of a small uniform perforation of a pipe, it might be appropriate to estimate pipe life by simply dividing the pipe wall thickness by the corrosion rate. More typically, the corrosion rate would be multiplied by a factor. In the case of pipe life, the corrosion rate factor seldom would be less than four, even in fairly uniform corrosion conditions. This assumes a multiplier of two for electrolytic current density distribution across the corroding area and a multiplier of two for a hoop-stress safety factor. Hence, the estimated pipe life would be one-quarter the previous case of a small, uniform perforation of a pipe.

In addition to metal loss from stray-current discharge, stray current can be deleterious in areas where current flows onto a structure. Electrochemical reactions at the metal/soil interface where current flows onto a structure can result in high pH (caustic) buildup and also hydrogen evolution. Amphoteric metals such as lead and aluminum dissolve in high-pH/caustic environments. Hydrogen evolution causes embrittlement of high-strength steel and disbondment of protective coatings.

Electric Rail System Design for Corrosion Control

Stray current can be minimized by transit system designs that encourage current flow through the rail and discourage current flow from the rail to earth. In the past, electric transit systems were constructed with poorly bonded rail, noninsulated embedded track, and directly grounded substations. As a consequence, large magnitude stray currents occurred along the length of the transit system. Today stray current is mitigated, in part, by construction with continuously welded and cross-bonded rail, and high resistance rail-to-earth track, referred to as track-to-earth resistance since the rails are cross

bonded. Substations are closely spaced and are either diode grounded or ungrounded. These design elements are illustrated in the electrical schematic of a single train powered by a single substation in Fig. 1. Current flow is from the substation, through the overhead wire catenary system (OCS), and back to the substation through both the track and the earth.

The quantitative effects of transit system design elements are demonstrated by considering earth as a parallel conductor to the track. The traction current will flow in the two parallel paths, the track and the earth. The magnitude of the stray current is the traction current times the ratio of the track resistance to the overall circuit resistance:

$$I_{UG} = I_{TOTAL} \frac{R_{TRACK}}{(R_{TRACK} + 2R_{TTE\ UG})} \quad (\text{Eq 3a})$$

$$I_{DG} = I_{TOTAL} \frac{R_{TRACK}}{(R_{TRACK} + R_{GM} + R_{TTE\ DG})} \quad (\text{Eq 3b})$$

where I_{UG} is the stray current in an ungrounded system, I_{DG} is the stray current in a diode-grounded system, I_{TOTAL} is the total traction current, R_{TRACK} is the track resistance, R_{GM} is the ground mat resistance, $R_{TTE\ UG}$ is the track-to-earth resistance in an ungrounded system, and $R_{TTE\ DG}$ is the track-to-earth resistance in a diode-grounded system.

Stray current is minimized by a low track resistance and a high track-to-earth resistance. Note that for the ungrounded system, stray-current discharge is shown, in Fig. 1(a), to occur over one-half the track length, and stray-current return is shown to occur over the other half of the

track length. For the diode-grounded circuit, the stray-current discharge is shown in Fig. 1(b) to occur over the entire length of the track, and the stray-current return is shown to occur at the diode ground mat. The diode ground mat is an engineered low-resistance ground return.

Track (Conductor) Resistance. Rails are continuously welded and cross bonded to minimize the electrical resistance of the track. Rails are cross bonded with electric cables so that the four rails of two-train track (typical of bidirectional traffic) are electrically continuous. The resistance of a single rail is approximately 0.01 $\Omega/1000$ ft or 0.0025 $\Omega/1000$ foot of four-rail track that is cross bonded.

Track-to-earth resistance is historically expressed in units of $\Omega/1000$ ft (1 $\Omega/1000$ ft is 0.3 Ω/km). Noninsulated tie-and-ballast track with wooden ties, steel spikes, and clean rock ballast has a resistance on the order of 10 to 100 $\Omega/1000$ ft of four-rail track. Insulated tie-and-ballast track with concrete ties, insulated fastener clips, and clean rock ballast has a resistance on the order of 100 to 500 $\Omega/1000$ ft of four-rail track. Insulated direct fixation track (track anchored onto a concrete slab) also has a resistance on the order of 100 to 500 $\Omega/1000$ ft of four-rail track.

Figure 2 shows noninsulated tie-and-ballast track with wooden ties, steel spikes, and rock ballast that is fouled with soil fines and moss. This track might have a resistance less than 10 $\Omega/1000$ ft of four-rail track. Figure 3 shows insulated tie-and-ballast track with concrete ties. Note the clean, well-drained ballast and insulating clips between the ties and rails. This track might have a resistance on the order of 500 $\Omega/1000$ ft of four-rail track.

Insulated embedded track is claimed to provide exceedingly high track-to-earth resistance. Indeed, sections of embedded track with boot-type insulation have been measured at 10,000 and even 100,000 $\Omega/1000$ ft of four-rail track. However, low-resistance point source grounds are possible because of construction defects. Sensitivity analysis, by a calculation of electrode resistance, shows that a single flaw, or several small flaws, will lower the track section resis-

tance to 100 $\Omega/1000$ ft. Direct shorts can result in a point source short of 10 Ω or less.

For tie-and-ballast and direct fixation tracks, there is fairly uniform current discharge along the track given the presumed condition of stray current due to uniform leakage at each fastener. Directly shorted fasteners are point source shorts. These shorts are exposed and can be readily located and repaired. In contrast, a short in an insulated embedded track system is more difficult to locate and repair because the insulated rail is cast into the concrete slab. Typical defects in the installation of insulated embedded track include damage to the insulating elastomeric boot, inadequate boot splice connections, and shorts to the gauge bar and surrounding track slab rebar.

Figure 4 shows the complexity of embedded track construction. The photograph shows a rail with an insulating boot, a gauge bar, and surrounding track slab rebar. The boot must be protected during storage, handling, positioning, and welding of the rail and during rebar installation and placing of concrete.

Figure 5 shows an insulated embedded rail constructed with a potting compound that is now degraded from environmental and mechanical damage. Figure 6 shows construction of a track slab with an insulating elastomeric boot. Although the elastomeric boot is a promising construction technique, the remaining concern is

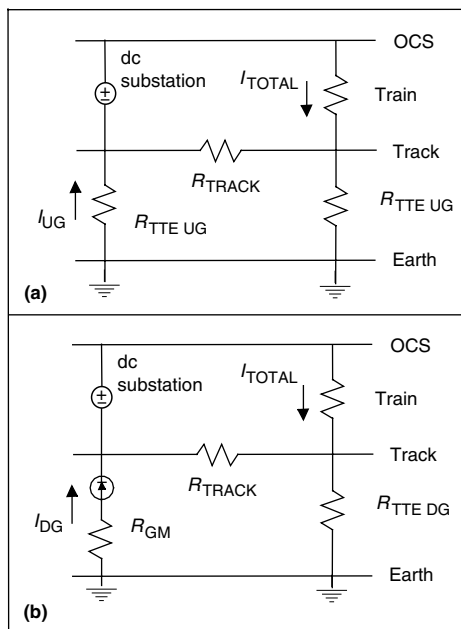

Fig. 1 Electrical schematic of (a) ungrounded and (b) diode-grounded rail systems. Refer to the corresponding text, and in particular Eq 3(a) and (b), for an explanation of the abbreviations shown in this figure.

Fig. 2 Noninsulated tie-and-ballast, with wooden ties, metal spikes, and ballast rock that is fouled with soil fines and moss

Fig. 3 Insulated tie-and-ballast track with concrete ties and insulated clips. The ballast rock is clean and well-drained; however, leaves are accumulating.

Fig. 4 Embedded track slab construction, rail with insulating boot held by gauge bar and surrounded by the slab reinforcing steel.

that the product does not have a long performance history, and repair of a material failure may be costly and disruptive. Figure 7 shows a boot with separation of the splice connection and damage to the running surface.

Substation Spacing and Grounding. The spacing of substations along a proposed electric rail line is a key element that determines the stray current in a system. Closely spaced substations lessen the length of track between stations, thereby reducing the track circuit resistance and increasing the track-to-earth resistance. This lowers the magnitude of stray current. Substations can be ungrounded, diode grounded, or solidly grounded.

The diodes of diode-grounded substations prevent current discharge from the ground mat and the direction of stray-current flow is from the track, through the earth, to the ground mat. The diodes also have a forward bias that prevents current flow until a threshold voltage is exceeded. However, the threshold voltage can be regularly exceeded, causing the diodes to conduct often. When the diodes are conducting, there is an additional concern that stray current can be concentrated around the substation ground mat and cause corrosion at utilities neighboring and serving the substation.

Systems with ungrounded substations can have a greater track-to-earth circuit resistance than systems with diode-grounded substations when the diode is conducting. As illustrated in

Fig. 1(a), in an ungrounded system, half of the track length contributes to current discharge, and half of the track length contributes to current return, so the track resistance is $2 R_{TTE\ UG}$. In contrast, diode-grounded systems have a relatively low resistance ground mat ($R_{GM} \ll R_{TTE\ DG}$), and when the diode is conducting, current discharges from the full length of track to the ground mat. Typical resistances of diode system ground mats vary from 0.01 to 0.1 Ω where the direct current (dc) ground mat is cross bonded with the substation alternating current (ac) ground mat, 0.1 to 1.0 Ω for a low-resistance dc ground mat, and 1.0 to 10 Ω or greater for a high-resistance dc ground mat.

Considering the case of an electric rail system of 2 miles of track at 200 Ω /1000 ft ($R_{TTE\ DG} \approx 20\ \Omega$, $R_{TTE\ UG} \approx 40\ \Omega$), and a diode ground mat less than 1 Ω ($R_{GM} \ll R_{TTE\ DG}$), the stray current would be approximately four-fold greater when the diode is conducting ($I_{DG} \approx 1/R_{TTE\ DG} \approx 1/20$) than when the system is ungrounded ($I_{UG} \approx 1/(2 R_{TTE\ UG}) \approx 1/80$). An electric rail system with a high resistance diode-ground mat and/or a low track-to-earth resistance would be, operationally, intermediate between a diode-grounded and ungrounded system. The actual difference in overall stray current between an ungrounded and a diode-grounded system is dependent on all elements of system design and construction.

The principles presented for the simple case of a single train and a single substation, shown in Eq 3(a) and 3(b), are fundamentally correct and instructive regarding corrosion-control design elements. In practice, electric rail transit systems are modeled to simulate the more realistic case of multiple moving trains and multiple substations, where long sections of track can discharge to distant track and to distant substation ground mats. These simulations are used for both the design of the electric rail system and to determine the stray-current exposure to neighboring utilities.

Another corrosion consideration regarding ungrounded versus diode-grounded electric rail systems is the direction of current flow between the track and the earth. In an ungrounded system there is current reversal to and from the track

at any location because, as the train travels, the location of the electric load changes. In a diode-grounded system, the current flow is principally from the track to the earth and back through the diode-ground mat because the track has a much greater resistance than the diode-ground mat.

Figure 8 shows pipe-to-soil measurements made during the monitoring of a cathodically protected pipeline at a light rail crossing. During the monitoring shown in Fig. 8(a), the transit system was operated diode grounded, and stray-current flow was always from the track and toward the pipe in the immediate area of the crossing. The pipe-to-soil potential was always more negative than -1.0 V.

During monitoring shown in Fig. 8(b), the transit system was operated ungrounded, and current flow was both to and from the track. The centerline measurement of pipe-to-soil potential is more positive than -1.0 V. Stray-current flow reversed with train movement, and since there is the possibility of current flow from the pipe to the track, there is an increased prospect of corrosion of the pipe at the track crossing. This corrosion mechanism of closely coupled stray current from the pipe to the track can concentrate corrosion at this location. It is of particular concern because there is a multitude of utility crossings along an electric rail system. The location noted in Fig. 8 had been operated for 20 years as a diode-grounded system with an insulated embedded track. The rail had appreciable corrosion where installation of the elastomeric boot was inadequate.

Fig. 5 Embedded track insulated with potting compound, now degraded from mechanical and environmental damage.

Fig. 6 Embedded track insulated with a surrounding elastomeric boot that is visible at a construction joint in the track slab.

Fig. 7 Embedded track with boot damage. Boot shows surface raveling and an open gap at a splice connection.

(a)

(b)

Fig. 8 Substations operated diode-grounded (a) and operated ungrounded (b). CSE, copper/copper sulfate reference electrode

There are some advantages to electric rail system operations having substations ungrounded (Ref 1, 2). When operated ungrounded, the rail voltage varies both positive and negative, and absolute voltages are lower. In some circumstances, it may be possible to better detect ground fault conditions if the system is ungrounded rather than diode grounded. In respect to corrosion control, overall stray current could be reduced when the system is ungrounded because of the increase in the overall circuit resistance. Also, the corrosion of rail is more evenly distributed because the location of the current discharge and return changes as the train moves.

In the case of a system with solidly grounded substations, the overall circuit resistance will be particularly low and the magnitude of stray current appreciably higher than either a diode-grounded or ungrounded system. If the substation is grounded directly or indirectly to neighboring utilities, stray current will occur over a greatly expanded area. Critical facilities are sometimes protected in this manner by providing an interference bond. However, this is of necessity and not favored in new construction.

Trains and Station Platforms. The total traction current shown in Eq 3(a) and 3(b) is largely determined by train operation. Two-car trains (called “consists”) have twice the current load of a single-car train, and the heavier the train and passenger weight the greater the traction current. Streetcars and light rails require lower peak traction currents in downtown areas where speed and acceleration are curtailed. The peak traction current of a quickly accelerating train is more than an order of magnitude greater than the average running load.

Underground utilities should be considered when installing station platforms because stray current is likely to be greater at these locations. Acceleration, deceleration, and the associated increase in traction current occur near station platforms, as well as at traffic signals and hills. Deceleration affects traction current when trains use regenerative braking, and the motor is used to generate power that is fed back into the system. In downtown areas there will likely be a platform every few blocks in contrast to suburban areas where platforms might be miles apart.

Track Slab Design. The track slab of embedded rail is designed to support the train and to bridge a distance that accommodates minor underground utility work, often a span of less than 10 ft (3 m). Figure 9 shows utility installation under an existing track slab.

To protect the track slab reinforcing steel from stray-current corrosion, the rebar may be coated and installed electrically discontinuous, or the rail insulation may provide sufficient stray-current control and standard bare rebar construction is used.

Alternately, rebar mats can be installed bare with welded rebar to provide electrical continuity, though wire-tie construction is incidentally electrically continuous. Sometimes rebar

mats are characterized as “collector mats,” believed to direct the preponderance of stray current back to the rail. This characterization does not consider that the rebar mat is a parallel conductor in equilibrium with the soil electric field strength along its length. In response to the corollary concern of a rebar mat concentrating ground current effects at utility crossings, the track slab design can include dielectric insulation, such as a dielectric membrane between the slab and the earth. Dielectric insulation of the track slab also increases the track-to-earth resistance at that location and provides redundancy at critical utility crossings.

Construction Quality Acceptance. To avoid low-resistance point shorts, the acceptance criterion for track-to-earth resistance should require resistance testing on suitably short sections of track or require alternate methods that detect low-resistance shorts. Often, test measurements are made on long sections of track and are prorated to uniform values specified as $\Omega/1000$ ft. This can be misleading because the corrosion caused by uniformly distributed stray current is typically less a concern than the situation where there is actually large magnitude stray current from a point source. A criteria of $100 \Omega/1000$ ft that is prorated could result in acceptance of ten 1000Ω shorts in a 1000 ft section, or one 100Ω short in a 1000 ft section, or one 20Ω short in a 5000 ft section. All these equate to a prorated $100 \Omega/1000$ ft. Specifying an actual test length limits the possible magnitude of a short that can go undetected. If the actual test section length were required to be 1000 ft, then the lowest resistance single short accepted would be a minimum of 100Ω .

In the case of embedded track, locating shorts and flaws in insulation requires considerable field testing. Repairs require jackhammer excavation in the track slab. Track construction methods should include flaw (holiday) detection just prior to placing concrete. At that time, an insulating boot can be tested with a high-voltage holiday detector. After concrete encasement, flaws can be detected by techniques similar to those used to find flaws in buried pipeline coatings, typically, radio frequency holiday detectors and voltage gradient measurements.

Electric Rail Construction Impacts on Underground Utilities

Electric streetcar trolleys and light rails are intended to serve urban areas. These are often downtown areas with congested traffic, street-level businesses, and myriad large-sized underground utilities serving the area. To minimize project cost and disruption to the public, transit authorities endeavor to minimize utility relocations. This consideration should be a balance between initial capital construction and the continuing cost and disruption caused by utility maintenance.

Despite the best transit design, utilities are impacted by the project. Some underground

utility relocation will be necessary to accommodate electric rail transit construction. Electric rail transit construction impacts to underground utility systems can be characterized as direct physical interferences, maintenance access encroachments, and stray-current corrosion. These impacts to the utilities are evaluated together to ensure uniform integrity and to balance risk and cost.

Direct Physical Interferences. Construction of electric rail tracks, catenary poles, and duct banks obviously requires utility relocations where there is a direct physical interference. There may be additional physical interferences from street improvements caused by, or in conjunction with, the transit project. These could be from road alignment and grade changes, construction of retaining walls and bridges, sidewalks, drainage, streetlights, and traffic signals. Moreover, there may be direct impacts of other utilities relocating to accommodate construction. Typical utilities that relocate and compete for space in the public right-of-way include water, sewer, natural gas and fuel lines, electric power, communications, and traffic utilities. Finding space for every utility in the congested right-of-way becomes a challenge.

Maintenance Access Encroachments. Utilities located directly underneath or in close proximity to the proposed tracks are inaccessible for routine maintenance, utility operations, and future improvements. Electric rail systems are usually considered regional facilities with uninterrupted service during revenue hours. Trains normally run every 5 to 15 min during operating hours (which are often called the revenue hours), 7 days a week. Nonrevenue hours are generally 2:30 to 4 AM and are the only hours when trains are not running that utility work can occur adjacent to tracks without impeding the trains.

Fig. 9 Utility work at existing track slab. Tracks remain operational during excavation; however, utility work stops and moves out of the way to allow train to pass unimpeded.

This limits utility operations, maintenance, and construction to a restrictive transit schedule unless the utilities are located a sufficient distance from the tracks such that work can occur without interrupting the transit operations.

Safety requirements limit crews from working close to moving trains or close to the high-voltage overhead catenary power line. Excavation under or adjacent to the track is limited to prevent undermining the rail system, to minimize weight load on the existing utility, and to protect the workers in the trench. Excavation parallel to a track can be more problematic than utility crossings under a track, since work parallel to the track would require shoring systems to provide geotechnical support to the trench in addition to protecting the workers. Shoring can be a formidable task given the proximity of neighboring utilities. In addition, trench work parallel to the track is problematic in the physical constraints of the heavy equipment needed to install, maintain, and replace utilities. The construction equipment straddles the utility trench and can encroach on the track right-of-way and tangle with the OCS or impede the movement of the train.

Stray-Current Corrosion. Many existing buried utilities are bare metal. These include concentric neutrals on power lines, lead sheathed communication cables, steel fuel lines, and water lines that are typically gray and ductile cast iron with copper service lines. Portions of the water lines can be electrically continuous because of standard construction methods, that is, leaded joints for cast iron and mechanically restrained joints for ductile iron. Fuel lines are usually coated steel with cathodic protection. The concerns for electric rail construction are stray-current corrosion of the bare metal utilities and

electric rail interference to cathodically protected utilities.

Figures 10(a) and (b) show recording chart data of track-to-earth currents and the corresponding earth gradients, resulting from an intentional test short on an ungrounded rail system. The earth gradients are potential (voltage) measurements between a copper/copper sulfate electrode reference cell (CSE) at a remote location and a CSE reference cell in an area of interest. The data are also shown in a cumulative frequency graph used to determine time average values (Fig. 10c and d). The chart profiles are characteristic signatures of multiple train movements. The change in the readings through time is associated with train location and acceleration.

Measurements of current flow through the test short (Fig. 10a), show reversals with both discharge and pickup at the short. The time average current discharge of the short was approximately 20% of peak. Computations of electrolytic corrosion effects are based on time average current.

The earth gradient profile (Fig. 10b), corresponds directly to the current flow shown in Fig. 10(a). Using Ohm's law, the test short is computed to have a constant track-to-earth short resistance of approximately 100 Ω :

$$E = IR \quad (\text{Eq 4})$$

where E is the track-to-earth voltage at a given time, (V), I is the track-to-earth current at a given time, (A), and R is the track-to-earth resistance constant (Ω).

The expression track-to-earth resistance is somewhat misleading in that the resistance is not a contact resistance, but is the resistance of current flow between remote earth and the structure. The resistance is a consequence of soil

resistivity and current density. The current density is minimal in remote earth, but streamlines of current (current density) converge in the vicinity of the electrode.

The resulting gradient is paramount in stray-current control and is shown in Fig. 11. Figure 11 shows two curves—the current density in soil resulting from a hemispherical field such as a discrete short, and a hemicylindrical field representing uniform discharge along the track. The figure compares the current density at 1 ft (0.3 m) distance from a current source through a 25 ft (7.6 m) distance. These are common distances for utility clearances in street construction. As a useful field approximation, note that the geometric relationship between current density in the soil and distance from a current source is such that current density is reduced roughly half or more with each doubling of distance from the current source. The change in current density through distance is characteristically a rectangular hyperbola ($y = c/x$) as shown in both the hemispherical and hemicylindrical case.

This geometric relationship between current density and distance can be seen in the comparison on the chart recording of Fig. 10(b) with the simultaneous chart recording of Fig. 12. The earth gradient between remote earth and the immediate vicinity of the short, Fig. 10(b), is roughly an order of magnitude greater than the gradient between remote earth and a location

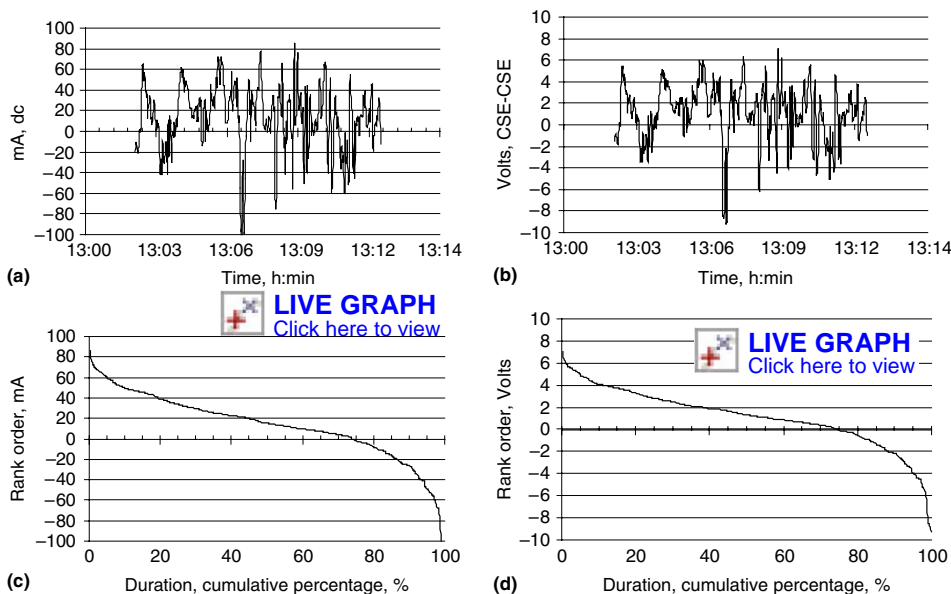

Fig. 10 Track-to-earth current (a) and earth gradient (b) for a 100 Ω test short on an ungrounded embedded track system and their respective time durations (c) and (d). The CSE reference cells were located at the short and remote (175 ft, or 53.3 m).

Fig. 11 Relative current density in soil as a function of distance from the current source, with the maximum current density of interest 1 ft (0.3 m) from the source.

Fig. 12 Earth gradient for a 100 Ω test short on an ungrounded embedded track system. The CSE reference cells were located 25 ft (7.6 m) from the short and remote (175 ft, or 53.3 m). Refer to Fig. 10(b). See text for details.

25 ft from the short (Fig. 12). Note that Fig. 12 voltage is graphed at $1/10$ scale of Fig. 10(b) and that the gradient profiles are analogous.

An engineering approach to electric rail stray current can be developed from "Grounding Principles and Practice—Fundamental Considerations on Ground Currents" (Ref 3), which presents the case of a short pipe in an extended field, a long pipe in a limited field, and a long pipe in an extended field. Ground currents are addressed in terms of current density (current per cross-sectional area), electric field strength (as the product of current density and soil resistivity), and voltage (as the line integral of field strength).

Equation 5(a) given below can be used to calculate stray current for the case of a short bare pipe in an extended field. Only current density in the soil and the pipe dimensions are necessary to estimate stray-current corrosion. Electrolytic current density, as the average entrance and exit current density over the surface of a pipe, is derived as a function of electric field strength and the ground resistance of the structure. The calculation is independent of soil resistivity because soil resistivity cancels in the relationship of electric field strength and structure-to-earth resistance. Equation 5(b) calculates the case of a long pipe in a limited ground field. Again, the distance between the pipe and the current source is a determinant of corrosion. Equation 5(c) calculates the case of a long pipe in an extended field. The distance between the pipe and current source is not predominant. The ratio of the soil/metal resistivity is so great (roughly 10^9) that in the equilibrium of electric field strength between metal and soil, large cross sections of soil are involved. In this case, electric rail influence can extend over wide areas and long distances. In urban areas, the effects might be spread over a multitude of structures including building foundations (most often electrically continuous through utility connections). In suburban and rural areas, the effect might be concentrated on the few parallel utility structures. Equations 5(a) to (c) are presented as:

$$i_{\text{avg pipe}} = i_{\text{soil}} \frac{l}{\ln\left(2\frac{l}{a}\right)} \quad (\text{Eq 5a})$$

$$i_{\text{max pipe}} = \frac{I_{\text{soil}}}{\pi a S} \frac{1}{\ln\left(4\frac{S}{a}\right)} \quad (\text{Eq 5b})$$

$$\frac{i_{\text{pipe}}}{i_{\text{soil}}} = \frac{e_{\text{pipe}}/\rho_{\text{pipe}}}{e_{\text{soil}}/\rho_{\text{soil}}} = \frac{\rho_{\text{soil}}}{\rho_{\text{pipe}}} \quad (\text{Eq 5c})$$

where a is the pipe radius (ft), e_{pipe} is the electric field strength of pipe (V/ft), e_{soil} is the electric field strength of soil (V/ft), i_{pipe} is the current density in pipe (A/ft²), $i_{\text{avg pipe}}$ is the average surface current density over pipe half length (A/ft²), $i_{\text{max pipe}}$ is the maximum surface current density over pipe half length (A/ft²), i_{soil} is the current density in soil (A/ft²), I_{soil} is the current in soil from electrode (A), l is the half length pipe (ft), ρ_{pipe} is the resistivity of pipe ($\Omega \cdot \text{ft}$), ρ_{soil} is the resistivity of soil ($\Omega \cdot \text{ft}$), and S is the distance between pipe and current source (ft).

The principals presented in Ref 3 have been adapted to utility work in electric rail corridors (Ref 4). Graphical methods are provided to quantitatively assess stray-current effects on existing bare utilities for several scenarios, including uniform conditions along the track, areas of failed track insulation, and point source track shorts. The approach is to elect an acceptable corrosion rate and compare the associated ground current to anticipated rail system characteristics. Dynamic models of track potentials and stray current can be utilized but are not necessary.

The graphical approach provides for sensitivity analysis by demonstrating the effects of changed rail conditions and also suggests reasonable values to assume in solving otherwise indeterminate problems.

Matrix tables are then used to assess risk. For example, a design that is contingent on installing and maintaining an exceedingly high track-to-earth resistance can be scrutinized to show the effects of a compromised or degraded installation. The matrix tables are also used to find a convergence of design criteria that balances risk. Presumably, in cases where there is adequate maintenance access and/or interruption of transit is a viable option, a greater corrosion risk might be acceptable. Alternately, where utility access is problematic and/or disruption of transit service is not an option, more stringent corrosion control would be required.

Table 1 shows the application of a matrix table used in a project to evaluate possible relocation of waterlines proximate to a light rail (Ref 4). The designer may consider that a 100 Ω short is a likely possibility. Using the values presented in the table, a long pipe located within 3 ft (0.9 m) of a 100 Ω short will corrode at an unacceptable rate. However, at 10 ft (3 m) distance, a 20 Ω short would result in a moderate corrosion rate and a 20 Ω short may be considered unlikely. Note that in this case, stray current from low-resistance shorts governs, and that track with a uniform resistance is less of a concern regarding stray current. To maximize the benefit to

project cost, the corrosion risk associated with distance from the track is then compared to the distance criteria for access and maintenance requirements. This approach to engineering uncertainty, the use of sensitivity studies, graphical solutions, and decision matrices are discussed in Ref 5.

Electric rail construction is used most often on shared transportation right-of-ways that have buried utilities. The utility engineers must elect to either leave the utilities that neighbor electric rail in place or relocate the utilities. If the utilities are to be relocated in place or at a further distance, mitigation can include the use of alternate nonmetallic materials, casings, and cathodic protection. Corrosion-control measures can also include mitigation bonds and galvanic drains; however, there are common misunderstandings in their use, and the reader's review of a primer on the subject is suggested (Ref 6).

Utility Construction and Funding

By their nature, large electric rail projects are complicated and challenging. There are a number of issues and criteria to be considered while resolving conflicts between existing utilities and electric rails (Ref 7, 8).

Early involvement by utility owners in the design phase of the transit system is essential to assess the need and cost of relocations. Utility relocation and coordination can be critical variables affecting transit project schedule, scope, and budget. Early involvement allows utilities and project designers to proactively identify and resolve conflicts that could otherwise delay design and construction.

Construction issues involve staging and sequencing of work and mitigating traffic impacts and impacts to adjacent property owners, neighborhoods, and businesses. Construction sequencing and staging are interrelated. Usually, utility work is done in advance of the main civil track construction. Utilities must provide uninterrupted service to customers, and that might

Table 1 Risk assessment matrix

Based on a selected current density of 0.001 A/ft² for an acceptable corrosion rate of the pipe. See text for details.

Design separation pipe-to-rail, ft	Maximum allowable stray current, mA	Equivalent short resistance, Ω	Risk
Long pipe, limited ground field			
3	22	100	High/likely
10	200	20	Moderate/unlikely
50	670	3	Low/unlikely
Short pipe, limited ground field—hemispherical current source field			
3	15	100	High/likely
10	170	10	Moderate/unlikely
50	4300	0.5	Low/unlikely
Short pipe, limited ground field—hemicylindrical current source field			
3	50 mA/10 ft	0.5 Ω /1000 ft = 50 Ω /10 ft	Low/unlikely
10	170 mA/10 ft	0.1 Ω /1000 ft = 10 Ω /10 ft	Low/unlikely
50	850 mA/10 ft	0.02 Ω /1000 ft = 2 Ω /10 ft	Low/unlikely

Units used in this table are traditional for the industry. Source: Ref 4

require alternate service arrangements during construction. There are usually operational and seasonal restrictions that limit when work can occur on the utility system. For instance, water-supply systems often cannot be taken out of service during peak season, which is most often May to October. For a natural gas utility, the peak season is during the winter and the utility tries to limit their downtime to the summer months. Often each utility must work in turn, rather than concurrently. For safety reasons, no utility can work in the area while the power poles and electrical lines are being relocated. In underground work, typically, the deepest utility relocates first and shallowest relocates last. However, sometimes, other sequencing arrangements are necessary. With limited routes for relocation available, there may also be an issue of where utilities can physically locate.

Construction and maintenance limitations arise in accommodating electric rail corridors (Ref 7). Figures 13 and 14 illustrate the challenge of installing mains or relocating pipelines to accommodate the electric rail. Figure 13 shows a typical choke point where several utilities converge to make way for the new electric rail next to an existing viaduct. Since the viaduct supports half of the roadway, only half of the right-of-way is available for utilities. With the proposed light rail over the centerline of the roadway and an existing 96 in. (2.44 m) sewer occupying the travel lane, there is little room for remaining utilities. Figure 14 shows the vertical offset crossing of a 24 in. (0.6 m) ductile iron main crossing a 12 in. (0.3 m) main. Utility relocations often require vertical offsets to route under and over existing structures.

Working Clearances. Utility relocations are designed to meet current federal, state, and local regulations and industry standards. Regulations cover safety clearances that are required for permanent and temporary obstructions. Designs typically satisfy both conditions. When it is not possible, designs address permanent safety requirements, and requirements for temporary safe working conditions are satisfied as they arise during construction, operations, and maintenance.

A design envelope for clearances around an electric rail is shown in Fig. 15. Some of the safe clearance requirements affecting utilities in electric rail corridors are presented. There may be other clearance requirements—the listing is not all-inclusive and requirements may differ by jurisdiction. Aboveground clearances include the permanent and temporary clearances shown from overhead power lines and working clearances from moving trains. Underground clearances include the vertical distance to the track and a corresponding horizontal separation from the track, depending on depth of excavation. These clearances affect the decisions by utilities to relocate facilities and affect the decisions of where to relocate or install new facilities.

Safety clearances are governed by the Occupational Health and Safety Administration

(OSHA) and by various organizations responsible for industry standards. Notes 1 and 2 in Fig. 15 illustrate clearances from the overhead power lines, which are governed by OSHA, National Electrical Safety Code (NESC), and

the U.S. Department of Transportation. Oregon OSHA (Ref 9) and NESC (Ref 10) require a minimum 10 ft working clearance between overhead electrical lines (50 kV or less) and personnel or equipment (Fig. 15, note 1).

Fig. 13 Utility relocation encumbered by congestion. Utilities are squeezed together on one side of a proposed light rail. The other side of the road is a bridge viaduct.

Fig. 14 Vertical offset of a 24 in. (0.6 m) ductile iron water main to accommodate an existing 12 in. (0.3 m) main.

The NESC (Ref 11) requires an 18 ft (5.5 m) minimum vertical clearance over roadways for electrical lines 22 kV or less (Fig. 15, note 2). This same regulation requires a minimum of 22 ft (6.7 m) vertical clearance for electrical lines crossing railroads.

Electric transit systems that operate on fixed tracks are subject to regulations similar to heavy rail systems and governed by the Federal Transit Administration (FTA). Federal Rail Administration safety program (Ref 12) requires a working clearance between moving trains for road workers, rail workers, and their equipment (Fig. 15, note 3). This clearance, which is based on speed of the train, results in a 13 ft (4 m) worker clearance (Ref 12). The consequence of this federal regulation is that anyone working within this "fouling zone" is required to have flaggers, stop working, and move their equipment out of the way when a train is passing the work zone. During train operating hours (revenue hours), trains could be passing every 7 min. Oregon adopted the FTA regulations and applies them to all transit rail systems operating in Oregon (Ref 13 and 14). Typically, as a condition of the right-of-way permit to allow utilities to occupy a jurisdictions right-of-way, utilities and public agencies are required to conform to the rail safety standards.

There are national railroad standards (Ref 15 and 16) for cased crossings for flammable and nonflammable substances crossing railroads (Fig. 15, note 4). Gas and petroleum lines are subject to the requirements for flammable substances, while water lines are subject to the requirements for nonflammable substances. Casing lengths for nonflammable substances are required to extend at least two times the depth of the bottom of the casing below the railroad subgrade or extend at least 5 ft (1.5 m) beyond a 2-to-1 maximum excavation slope on each side of the track centerline, whichever is greater. Heavy rail companies may require the casings to extend across the entire length of the railroad right-of-way. Excavation by utilities is not allowed in the ballast or subballast zones (Ref 15, 16).

OSHA also restricts the maximum excavation slopes without shoring (Ref 17–19). A 1.5-to-1 is the steepest slope allowed, though a 2-to-1 maximum slope is preferred (Fig. 15, note 5).

Designing relocations to incorporate safety clearances provides access and continued utility operations and, more appropriately, assigns the cost to the capital project rather than shifting the cost to utility operations and maintenance.

Track Design Envelopes and Utility Design. Figure 16 illustrates differences in the track design envelope and its impacts on utilities. Figure 16(a) is the tie-and-ballast track section with a short ballast wall. This design is commonly used when a dedicated right-of-way can be provided adjacent to a roadway. Figure 16(b) is embedded track and is common when the electric rail transit shares the right-of-way with motorists. Figure 16(c) is the tie-and-ballast scenario often seen where the track system can

be located in a dedicated right-of-way, similar to the heavy rail systems. Figure 16(d) is a variation of Fig. 16(a) and (c), used when the track system is built at a different elevation from the adjacent

ground and there is insufficient room for side slopes.

Tie-and-ballast systems have deep design envelopes of 5 ft (1.5 m) or more, while

Fig. 15 Work clearances for utilities adjacent to and crossing under electric rail systems. Circled numbers are referred in the text as notes. Units of measure given in feet.

Fig. 16 Track design envelopes and their impacts on utilities crossings. Of particular interest is the depth from the top of the rail to the top of the casing, the length of the casing, and the vertical offset of the carrier pipe outside of the casing. (a) Tie-and-ballast adjacent to roadway. (b) Embedded track. (c) Tie-and-ballast in dedicated right-of-way. (d) Tie-and-ballast retaining wall. C/L, centerline

embedded track systems can have shallower envelopes, about 2 to 3 ft (0.6 to 0.9 m) in depth. Underground utilities are typically 2 or 3 ft (0.6 or 0.9 m) minimum depth. Most utilities will be physically impacted by tie-and-ballast construction because of the depth of the envelope. With embedded track, fewer utilities will be in direct physical conflict with the envelope construction.

The track slab design can be a critical cost factor because it can govern utility relocations. A shallow track slab design that incorporates the electric rail "utilidor" (utility corridor for the track system duct banks and track drainage) near the surface might allow for utility crossings in the same trench configuration without elevation changes. Elevation changes entail vertical offsets and often require a deep excavation to clear other neighboring utilities. Figure 16(b) illustrates the benefit of replacing a pipe in the existing configuration without elevation changes. Note, an offset is required if there is an elevation change, and often the elevation change must be particularly deep to go under conflicting interferences. The deeper the excavation, the greater the cost and disruption of construction and the more difficult it is to later access the pipeline.

The Portland Water Bureau developed a 10 ft (3 m) separation criterion between the electric rail transit and the water facilities. This is considered a convergence in the design requirements for access, corrosion control, and cost/benefit. The clearance entails relocating parallel waterlines 10 ft (3 m) from the track edge and crossing pipelines are cased under the track with the casing extending 10 ft (3 m) from each side of the track edge.

Construction limitations often necessitate exceptions to this criterion. In downtown streets, sometimes there simply is not enough unoccupied space to install a utility pipe parallel or extend a casing the specified distance from the track. Then the requirement is augmented with secondary insulation of the track slab and/or upgrade of the pipeline materials and construction. This addresses corrosion control; however, access is compromised.

At times, construction must be site specific. Where there is a pipeline that cannot be taken out of service, a casing such as a box culvert can be built around the existing pipe. If there is insufficient space for the casing to extend beyond the permitted excavation slope, a retaining wall can be provided to permit access for maintenance without undermining the track. This provides access for maintenance and construction, but again access is compromised.

Utility Relocation Funding Issues. Utility relocations can be eligible for up to 100% reimbursement to a utility owner in accord with U.S. Department of Transportation rules, provided there are no state or local regulations prohibiting reimbursement. The term "relocation" includes "removing and reinstalling facilities, including necessary temporary facilities, acquiring necessary right-of-way for the new

location; moving, rearranging or changing the type of existing facilities; and taking any necessary safety and protective measures" (Ref 20, 21). The intent is to "restore the utility to a functional capacity equivalent to that in place." Often, municipally owned utilities are reimbursed for relocating facilities located in the public rights-of-way or in private easements. However, costs for relocating public non-municipal and private utilities might not be reimbursed. Nonreimbursed expenditures are passed on to the ratepayers in the cost of services.

There is limited funding for electric rail construction, and reimbursement funds are not available for electric rail expansion or other amenities, such as station enhancements. Electric rail projects are often coupled with urban development and city street improvement projects that are outside of transit funding, so there is an impetus to minimize utility reimbursement to make these amenities available.

After electric rail construction is complete, there continue to be long-range impacts on the utility system. There should be long-term agreements regarding any additional cost of operations, repairs, and damages to the utility and limited liability of the utility to the transit system.

Monitoring and Maintenance for Stray-Current Control

Stray currents affect both the electric rail facilities and neighboring utilities. Effective stray-current corrosion control requires ongoing monitoring and maintenance after construction.

Monitoring and Maintenance by the Transit Authority. Though corrosion control is inherent in the design of the electric rail, the transit authority must prevent upset operating conditions. If an inoperative substation is allowed to remain off-line, or if there is imbalance among substations, then these upset conditions essentially increase the distance between substations and, thereby, increase stray currents.

Transit systems are designed to shut down if there is a critical short of the high-voltage supply. However, there can be high-resistance shorts that allow continued operation but result in stray current. This is often caused by current flow around fouled insulators. Transit authorities routinely visually inspect for this during regular maintenance.

The track-to-earth resistance can be greatly lowered by shorts, inadvertent or from construction, or from fouling of the ballast or fouling around insulators on tie-and-ballast, direct fixation, or embedded track. Transit authorities have wash-down maintenance programs to clean fouled ballast and insulators.

Those systems with diode grounding can be monitored for stray current by measuring ground return through a return shunt. This can be used to immediately detect upset conditions and to monitor for long-term, system-wide, degra-

dation in stray-current control. Systems that are ungrounded can be monitored with proprietary stray-current monitoring based on track voltage signatures. However, presently these methods are sensitive only to very low-resistance shorts.

Radio frequency holiday short detection surveys are practical for rail line surveys. Earth gradient measurements are practical at fixed critical locations, such as utility crossings, but because gradients vary with train movements they are less practical for line surveys. This difficulty can be overcome in a track maintenance survey by impressing a fixed current and monitoring the gradient. Often both radio frequency and impressed gradients are used to locate and confirm a short.

Track slab design can include electrically segmented track sections with current shunts to monitor stray current in the steel reinforcement.

Actual corrosion damage to the transit system is monitored by inspection and maintenance operations, with particular attention to track, fasteners, and supports for the OCS.

Monitoring by the Utilities. Utilities can monitor earth gradients at critical locations, such as crossings. Earth gradient measurements between a reference cell proximate to the track and a remote reference cell produce a profile with a characteristic signature that correlates with train movement. All of the earth gradient charts presented in this article show the characteristic profile of the change in stray current through time when trains are moving past a fixed location.

This method is a measure of the rail system conditions, and it does not require test stations. Nor does this method require a connection to the electric rail system or a neighboring structure. For safety, work in the electric rail corridor requires the cooperation of the transit authority. A test connection to the track can cause a dangerous malfunction of the train signal, and personnel are exposed to train traffic and possibly high-voltage environments.

Figure 17 shows typical gradient measurements of tracks at noninsulated tie-and-ballast track (Fig. 17a), insulated tie-and-ballast track (Fig. 17b), embedded track insulated with potting compound (Fig. 17c), and embedded track insulated with an elastomeric boot (Fig. 17d). Note that the scale of Fig. 17(a) is tenfold greater than the others. The gradient for the noninsulated track is an order of magnitude greater than the gradient of the insulated track. This is because the track-to-earth resistance of the noninsulated track is much less than the insulated track systems. The gradient for the track insulated with a potting compound is appreciably greater than the gradient of the other examples of insulated track. The potting compound is failing and the track-to-earth resistance of this track is less than the other insulated track sections. The small bias around the baseline of gradient measurements can be attributed to natural variations in soil; however, an offset of 100 mV or greater might indicate a steady-state source of stray current.

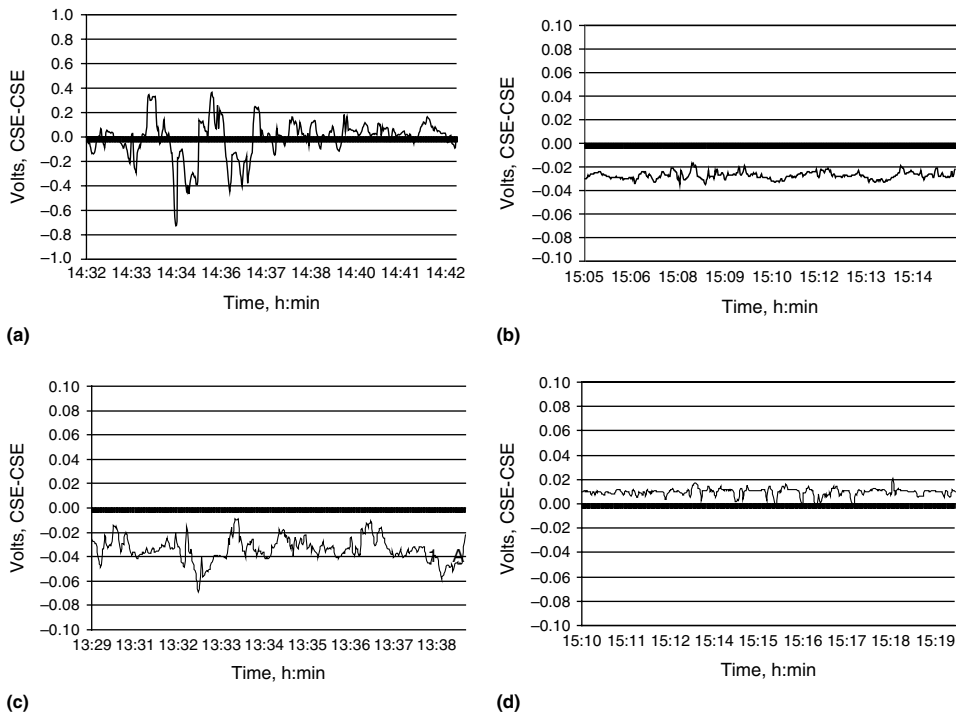

Fig. 17 Comparative track earth gradients. The tracks are not shorted. The CSE reference cells were located 15 ft from the track and remote (175 ft). See text for details.

With the cooperation of the transit authority, a calibrated track-to-earth test short can be used to provide a qualitative and semiquantitative measure of site-specific conditions. Subsequent profiles can be readily compared for changes and to verify that the original design assumptions are maintained. Figure 10(b) shows the measured effect of a 100 Ω short in an embedded track compared to the properly insulated section of embedded track in Fig. 17.

Utilities can install corrosion coupon monitoring test stations in critical locations such as crossings. Coupons are dimensioned bare areas made of the same material as the structure and electrically connected to the structure. Coupons are intended to represent the surface of the structure, and the coupon test stations are wired to measure polarized potentials and current flow (Ref 22).

Traditional corrosion test stations can also be installed. These test stations provide electrical connections to the utility and locations for reference cells and can include calibrated current spans or isolation joints with calibrated shunts for current measurement.

Test stations also facilitate utility line surveys. Line surveys include stray-current "exposure" and "mutual" surveys (Ref 23, 24). A method for locating high-exposure areas in electric rail corridors is to plot a profile of time-variant structure-to-soil potentials and simultaneous measurements of pipeline current (if available). This is done at several pipeline locations. In this way, areas of current pickup, current discharge, and locations of maximum exposure can be determined.

A mutual survey consists of simultaneous measurements of the source of stray current and structure-to-earth potentials. The data are graphed to verify a correlation between the transit operation and effects on the structure. The graph is commonly referred to as a beta curve when the data are a plot of the voltage between the structure and the transit system versus the structure-to-soil potential. A profile drawing of the pipeline locations versus the slopes of the beta curves indicates the locations of maximum exposure. The magnitude of the interference can be estimated by providing a calibrated test current that approximates the slope of the line at that location.

ACKNOWLEDGMENT

The authors wish to thank T. Heilig and K. Looijenga, Tri-County Metropolitan Transportation District of Oregon (Tri-Met), Portland, OR, for their cooperative stray-current testing and review.

Corrosion in Bridges and Highways

Jack Tinnea, Tinnea & Associates, LLC

BRIDGES AND HIGHWAYS are a core component of any country's or region's transportation system. In the United States, they comprise the largest public infrastructure system, consisting of approximately 583,000 bridges and 6.3 million kilometers (3.9 million miles) of public roads (Ref 1). Approximately 200,000 of those bridges are constructed of steel, 235,000 of conventionally reinforced concrete, 108,000 of prestressed concrete, and the balance constructed with other materials. These roads and highways range from quite primitive pavements with earth, gravel, or stone covered by a thin bituminous surface course to a continually reinforced portland cement concrete (PCC) roadway with or without a bituminous wear course.

This article is concerned with bridges and dowels and reinforcement used in PCC roadways. It is not that other types of roads and highways do not have maintenance issues. They do, but they do not suffer from corrosion problems. Bridges and reinforced PCC roadways do suffer from corrosion, and the cost of that corrosion is staggering. In the United States alone, a 2002 study reported annual direct corrosion costs of \$8.3 billion (Ref 2). Those costs included \$3.8 billion for bridge replacement, \$2 billion for bridge decks, \$2 billion to repair concrete substructures, and \$0.5 billion for maintenance coating of steel elements. Estimates of indirect costs to the bridge user, from traffic delay, detours, and lost productivity, were ten times the direct costs.

Highways and bridges are a ubiquitous component of the infrastructure, and the factors affecting their corrosion are varied and at times subtly complex. A brief overview is provided of the rise in awareness of the corrosion issues affecting bridges and highways and of the terminology used in following sections on highways and bridges. Much of the bridge and highway infrastructure is comprised of reinforced concrete, so a discussion of concrete and its role as an electrolyte follows. The next section addresses reinforcement, including conven-

tional, prestressed, cable stays, and corrosion-resistant reinforcement. Following this is a discussion of electrochemical methods for inspection and corrosion control for embedded reinforcement. The final section discusses the corrosion of metal bridges and corrosion control, including the use of weathering steels and coating systems.

A Historical Perspective and Current Control Strategies

Jack Tinnea, Tinnea & Associates, LLC

Over the past thirty years, both the popular media and professional published record have seen a somewhat explosive growth of articles concerning the decay and aging of public works facilities and buildings. Roads and bridges, with their potholes and rusted trusses, became a most visible icon for what is now collectively known as "the crumbling infrastructure," with much of that "crumbling" the result of corrosion processes.

History

The maintenance and repair of public works is an ancient art. It has come to prominence in the last quarter of the 20th century for several reasons. The first half of the 20th century saw structural engineers embrace reinforced concrete as a core building material. The second half of the 20th century saw an explosion in the building of highways and bridges and other infrastructure items in North America, in war-ravaged Europe and Asia, and in many developing countries. A review of the published literature over this

latter period shows an amazing growth of interest in corrosion of metals embedded in concrete (Ref 3).

It has long been known that seawater aggravates the corrosion of coastal bridges. People have attempted to address the corrosion of metals in marine environments since antiquity. Although engineers from the Roman Empire may have discussed the corrosion of iron bars grouted in stone or set in natural cement structures, published modern discussion of concrete-reinforcement corrosion dates to the early 20th century (Ref 4, 5). Much of the early work on reinforcing-steel corrosion addressed reinforced concrete in marine environments (Ref 5–7). In time, field experience and research showed that the processes that attack concrete, such as carbonation (Ref 8), alkali soils (Ref 9), and cracks (Ref 10), also can contribute to the corrosion of embedded reinforcement.

In addition to a rapid growth in the building of highways and bridges, the 1950s saw substantial growth in the use of roadway deicing salts in areas where snow and ice on the bridge decks adversely affected traffic safety. Because most of the early highway deicers contained chloride ions, this safety measure brought the ocean and its corrosion problems to inland areas. The earliest signs that the application of deicers caused corrosion problems appeared on metal elements at or above bridge decks. Included were steel items such as guardrails and truss elements that passing traffic would spray with slush and water containing chloride ions. Typically, these steel elements were protected by paint or galvanizing. Often, these coatings were not what today (2006) would be considered an integral component of a maintenance program. Rather, they were merely thin coats of paint applied over mill scale, with little or no surface preparation (Ref 2). The application of deicers produced a winter salt spray that greatly accelerated the rate of corrosion and subsequent coating failure.

In addition to causing corrosion problems for atmospherically exposed metals, chloride ions from deicers slowly diffuse through the concrete

to the surface of underlying steel reinforcement. When the concentration of chloride ions reaches a threshold level, corrosion commences. In time, as this corrosion proceeds, the buildup of corrosion products at the rebar-concrete interface generates sufficient pressure to crack the concrete. By the mid-1960s, highway engineers and scientists recognized that the marinelike problems with reinforcement corrosion had reached inland areas (Ref 11).

Changes in environmental regulations required owners and designers to look at highway and bridge corrosion in new ways. Lead- and chromate-bearing paints were the coating of choice for steel bridges during the North American interstate building boom from the early 1950s through the 1960s. In the United States, it is estimated that 80 to 90% of the over 200,000 steel bridges have lead-base coating systems (Ref 12, 13). Recoating of those structures requires integral lead abatement to provide protection to both the surrounding environment and the workers. Globally, there are over a half-million steel bridges, so the scale of maintenance painting is clearly enormous (Ref 14).

Environmental considerations carry over to today's (2006) concrete mix designs. Fly ash, a by-product from burning coal, is a pozzolanic material that can be used to replace cement. Pozzolans are finely divided mineral additions, or mineral admixtures, that, when mixed with calcium hydroxide, alkalis, and water, produce a cementitious material. Good mix designs, which incorporate fly ash or similar mineral admixtures, can accomplish several things. First, they find a productive use for a material that may otherwise be sent to a landfill. Second, their use reduces greenhouse gas emissions by allowing the cement content to be reduced. The U.S. Environmental Protection Agency (EPA) estimates that fly ash cement replacement in the United States reduced annual greenhouse emissions by approximately 2.7 million metric ton carbon equivalents (Ref 15). The EPA goes on to say that if all the fly ash produced in the United States were employed as a cement replacement in concrete mixes or other similar uses, such as stabilizing road beds, it would reduce greenhouse emissions by the equivalent of removing 13 million cars from the road for a year. In addition to environmental benefits, fly ash and its pozzolanic cousin, silica fume, produce concretes that are less permeable to chloride ions than comparable mixes that employ only portland cement.

Current Corrosion-Control Strategies

Strategies to combat corrosion in highways and bridges approach the problem from several directions. For reinforced concrete these include:

- Improvements in concrete and grout mix designs, including high-performance concretes

- Improvements in structure design and detailing
- Use of corrosion-resistant alloys or non-metallics as reinforcement
- Electrochemical techniques, including cathodic protection (CP), chloride extraction, and realkalization

For steel bridges and steel substructure components, the corrosion-control approaches include:

- Designs with structural elements out of the path of salt water that is sprayed by passing traffic
- Designing drains to avoid run-off water discharging onto substructure elements
- Development of nonhazardous high-performance coatings and primers
- Metallizing and thermal sprays
- Use of weathering steels

In addition to controlling corrosion, maintenance of bridges and highways must address the economic, health, and safety role these structures play. Some bridges are historic, so corrosion control and maintenance must also address this special issue. Fortunately, asset management has evolved considerably, and systems exist that assist owners in managing often complex infrastructures (Ref 16–19). Computerized bridge management systems available in the United States today (2006) include PONTIS and BRIDGIT. In Europe, the highways are managed today (2006) on an individual country basis. The Bridge Management in Europe (BRIME) project was undertaken to provide a framework for European highway network management that eventually could save billions of euros (Ref 20).

Many of the methods used to control corrosion in highways and bridges, such as coatings, corrosion-resistant metals, and CP, are discussed at length in these three volumes of Volume 13 of the *ASM Handbook*. Unique issues germane to the application of such methods to highways and bridges are detailed in the following sections. Because concrete is ubiquitous in highways and bridges, the properties of concrete that play a significant role in the corrosion of embedded reinforcement are also discussed.

Terminology

Corrosion practitioners and metallurgists new to the area of corrosion in highways and bridges can find themselves somewhat overwhelmed by terminology employed to describe the structures and their elements. Fortunately, there are excellent glossaries available, including some on the internet. Appendix III to the BRIME project report (Ref 20), "Glossary of Terms Used in Bridge Engineering," provides an extensive glossary of bridge engineering terminology and includes excellent graphics. For terms specific to concrete, refer to Ref 21 and the glossary in Ref 22.

Concrete: Implications for Corrosion

Jack Tinnea, Tinnea & Associates, LLC

Reinforced concrete is a heterogeneous composite material. Concrete affords corrosion protection for reinforcing steels by providing a physical barrier to the surrounding environment. In acting as a barrier coating, concrete provides shielding from aggressive ions such as chlorides. Concrete also acts as a barrier to oxygen, reducing its availability at the surface of the metal. However, the cement paste that binds concrete is a porous barrier. Actions taken that impede the ability of a concrete to transport ions will improve the ability of the concrete to protect embedded reinforcement.

Beyond being a barrier, concrete also provides embedded metals an alkaline environment. If other factors remain constant, the corrosion rate of steel in concrete is inversely proportional to the pore water pH and directly proportional to the oxygen and chloride ion content at the surface of the embedded steel. Movements of ions and gases in concrete are many orders of magnitude slower than that observed in seawater. Often, corrosion of metal embedded in concrete is in cathodic control, with the rate of corrosion limited by oxygen availability.

Although ubiquitous, concrete is a complex mixture of solid materials and voids whose chemistry and geometry greatly influence the corrosion behavior of embedded metals. It is comprised of sand and gravel bound in a cementitious matrix. The sand and gravel contained in concrete are known respectively as fine and coarse aggregate. The cement binder can be portland cement, activated blast furnace slag cement, or blends of portland cement and slag cements. Mineral admixtures may also be added to the cementitious matrix to improve corrosion resistance and as sustainable engineering practice.

In concrete, transport mechanisms frequently dominate the corrosion behavior of embedded metals. The observed corrosion rate is often under cathodic control governed by oxygen migration from the concrete surface to the surface of the embedded reinforcement. Figure 1 (Ref 23) shows key factors that impact the corrosion of metals embedded in concrete. Only the microclimate is included in this graphic; for large structures, macroclimate effects impact the entire structure, not just different structural elements or elements with isolated conditions.

The observed corrosion of steel in concrete often derives from the influence of multiple factors, as shown in Fig. 1, with different processes dominating at different scales. Transport in concrete principally occurs in pores and voids contained within the concrete. The scale of these voids runs from a few nanometers for

interparticle spacing to a few millimeters for entrapped air voids. That is a range of almost 7 orders of magnitude and is comparable in range to comparing an object the size of a basketball to another the size of the moon. That range of scales impacts reactant transport and hence corrosion. To properly resolve corrosion issues of reinforcement requires learning why concrete is more than an inert sponge that simply surrounds the metal.

Cement Chemistry

Portland cement is a mixture of silicates and aluminates formed at high temperature in a kiln and collectively known as clinker. The clinker is finely ground with a relatively small amount of a calcium sulfate known as gypsum. The resulting mixture is cementitious and reacts with water through a process known as hydration. Cements employed in concrete are known as hydraulic

cements. The reaction products that result from several simultaneous hydration processes form the microstructure of the cement binder in hardened concrete. Blast furnace slags are also used as cements. However, to achieve strength in a reasonable time, they must be activated. Slags can also be blended with portland cement. For a general introduction to concrete, there are several texts available that can be quite helpful to those dealing with corrosion of metals embedded in concrete (Ref 24, 25). For those who wish a more thorough discussion of the chemistries involved, Ref 26 provides a good start. Because the cement microstructure often dominates the transport of corrosion reactants and products, a thorough discussion of structure may be found in Ref 27.

Cement Compounds. The hardened cement paste (HCP) is comprised of three principal solid phases: a calcium-silicate hydrate (C-S-H), calcium hydroxide, and calcium sulfoaluminate hydrate. The C-S-H is an amorphous hydrate

with a variable composition. The C-S-H makes up more than 50% of the hydration product solid volume and is the greatest contributor to the strength of the cement. Calcium hydroxide comprises 20 to 25% of the paste solid volume, while the calcium aluminate hydrate volume is 10 to 15%. Because iron can substitute for aluminum, and SO_4^{2-} can be partially or fully replaced by other anions, such as 2OH^- , CO_3^{2-} , 2Cl^- , 2NO_3^- , and so on, the designation AFm is often used to refer to all HCP compositions with the same basic structure. The largest portion of the remaining solid volume comes from unhydrated cement residues (Ref 24).

Cement Paste Microstructure. Figures 2(a) through (c) show the HCP microstructure in successively greater magnification. This series of photographs covers 3 orders of magnitude in magnification. As can be seen, pore structure is a major component of HCP microstructure. The approximate range for pore sizes is from 0.1 to 1000 nm. Because most corrosion-related transport in sound concrete occurs in the capillary pores, it can be helpful to make a distinction between capillary pores and gel pores that are present in the C-S-H. One approach is to make a clear break at 10 nm (0.01 μm) (Ref 24, 27, 28), with the capillary pores being those with the larger effective radii. A second approach allows a bit of overlap, with small capillaries overlapping the range from 2.5 to 10 nm (0.0025 to 0.01 μm). The capillary pores are voids in the cement matrix that are remnants of water-filled space or relics from the hydration process. They exist as a random network of irregular pores that are interconnected by varying degrees.

Transport behavior in large capillaries, from 10,000 to 50 nm (10 to 0.05 μm), is not too different than that of bulk water (Ref 24, 25). From 50 to 10 nm (0.05 to 0.01 μm), surface forces within the capillaries start to play a role, and as their size diminishes, these forces can effectively increase water viscosity (Ref 28). Liquid-based transport in the gel pores of the C-S-H, those smaller than 2.5 nm (0.0025 μm), is felt to play only a minor role in corrosion (Ref 29), because the rate of liquid transport is approximately 1000 times slower in gel pores than that occurring in the capillary pores (Ref 30). From a corrosion standpoint, the capillary pores have historically received the greatest interest. They are most involved in the transport of chloride ions and oxygen and therefore have the greatest direct influence on the ability of a concrete to protect embedded steel reinforcement. However, water loss from gel pores can affect shrinkage and cracking. Cracking provides reactants with much wider pathways, which facilitate transport and accelerate corrosion.

The size and distribution of the capillary pores in concrete can change with time and variation in environmental conditions. If the hydration process can be continued, the formation of reaction products can reduce the effective pore size. The relative volume of water used to charge the concrete mix also impacts pore size and

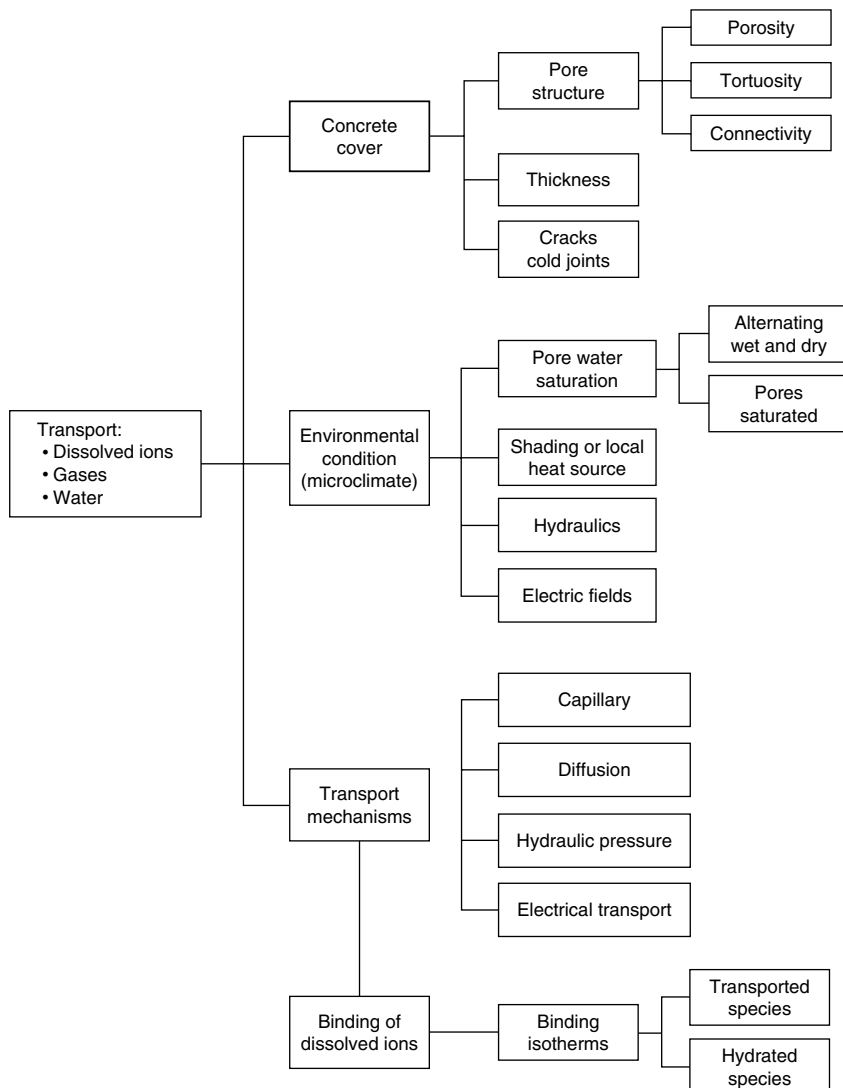

Fig. 1 Factors involved in corrosion of metals embedded in concrete. Adapted from Ref 23

distribution. A common term used to express that volume of water is the water-cement (w/c) ratio. Figure 3 shows the effect of w/c ratio on capillary pore size distribution as measured through mercury intrusion porosimetry (MIP) (Ref 31). Although MIP is not able to provide an absolute measure of pore size, Fig. 3 illustrates that reducing the w/c ratio yields smaller capillaries. A reduction of HCP capillary size will restrict transport of chloride ions and oxygen and thus impede corrosion of embedded steel.

The average size of the capillary pores is but one structural factor that influences the reactant transport of a given concrete. Three other factors are porosity, tortuosity, and connectivity. Po-

rosity is a measure of how much of the nominal volume of a concrete is occupied by the pores and entrained voids. As noted previously, increasing the w/c ratio will increase pore size, hence increase the porosity, and make the concrete more permeable. Capillary pores in concrete do not run in straight lines. Tortuosity describes the convolutions in these pathways and the impact of capillary narrowing. Increasing tortuosity slows the transport of ions and gases and hence can delay the onset of corrosion and slow its progress when initiated. Connectivity is a term that describes how well the pores are interconnected. Low connectivity means the pores are poorly interconnected, which will impede the transport of dissolved gases and ions and slow the onset and rate of corrosion. Conversely, high connectivity means it is easier for reactants to move, and corrosion will initiate sooner and with a higher subsequent rate. In summary, better control of reinforcement corrosion results by lowering both the porosity and connectivity of the concrete and by increasing the tortuosity of the pores.

Interfacial Transition Zone. The microstructure of HCP is modified near inclusions such as aggregates and reinforcing steel (Ref 32–34). This modification extends 20 to 50 μm (0.8 to 2.0 mils) away from the inclusion surface and is called the interfacial transition zone (ITZ). The origin of the ITZ is the wall effect, which reduces the density of small particles near much larger particles and is further enhanced by the effects of localized bleeding. This creates more space adjacent to the inclusion (aggregate, reinforcing steel) that must be filled by hydration products. The ITZ is characterized by enhanced porosity and a greater amount of cement hydration (Fig. 4). Computer simulations have shown that the ITZ around the aggregates can form a percolating network of porosity (Ref 34). The impact of ITZ and percolation should be considered when formulating concrete mix designs for reinforced structures in aggressive environments or where long life is desired.

Reactant Transport in Concrete. As discussed previously, the initiation of corrosion of steel reinforcement in concrete and its subsequent corrosion rate often depend on the transport rates of aggressive ions and oxygen within the concrete matrix. If the concrete contains large voids, rock pockets, or is cracked or delaminated, then capillary transport becomes much less an issue, because the movement of reactants within large defects is orders of magnitude more rapid than in sound concrete. Table 1 shows the transport modes common in concrete.

Depending on the situation, one or more modes may play a role. Simple ionic diffusion is usually the dominant mechanism of transport in the core of concrete structures. In the case of a retaining wall, where the soil behind the wall has a high chloride or sulfate concentration and hydrostatic pressure is present, permeability may be the larger transport mode. Several transport mechanisms may be at work within a vertical piling where lower areas are fully submerged in seawater while upper areas are exposed to the atmosphere. In this case, ionic diffusion may dominate in submerged areas below the tidal zone. Capillary suction may dominate locations above high water, where evaporation of pore

Table 1 Modes of transport in concrete		
Mode of transport	Basic parameter	Description
Permeability	K_p	Bulk flow of water or solution under a pressure head
Ionic diffusion	D	Diffusion of ions under a concentration gradient
Capillary suction	$\gamma/r(a)$	Spontaneous filling of very small pores (wicking)
Ionic mobility	u	Movement of ions under a potential gradient

(a) γ , surface tension of water; r , radius of the pore

water wicks water up from submerged areas or pulls seawater into the concrete after surface splashing. Within the tidal zone, which is between these two areas, a combination of modes is often at work.

pH. It is the high pH of concrete that provides a great deal of the corrosion protection to embedded steels. Figure 5 shows the inverse relationship between the corrosion rate of steel in concrete and pH (Ref 31). The liquid in the capillary pores is not pure water. Low-alkali cements yield a pH of approximately 13, while high-alkali cements can raise the pH to above 13.5 (Ref 24). At the elevated pH present in concrete, traditional low-alloy reinforcing steels, such as ASTM A706 (Ref 35), will develop a dense oxide coating that exhibits passive behavior similar to stainless steels. In fact, the corrosion potential of passive low-alloy reinforcements may be slightly more noble than stainless steel bars embedded in the same concrete. The corrosion inhibition by concrete is discussed in detail in the next section of this article.

Exclusive of its impact on corrosion rates, high alkali content can cause adverse reactions affecting concrete durability. Some aggregates used in concrete are sensitive to alkali content. This is known as alkali-aggregate reaction and can lead to cracking of the concrete, popping, or spalling. High alkali content can also lead to aesthetic issues such as staining of limestones and the formation of powdery deposits on the concrete surface (known as efflorescence).

Additives to Concrete

Although standard concrete mixes provide corrosion protection to concrete, materials are added to concrete to improve its handling characteristics during construction. Other added materials are actual by-products of waste generated in industry or electrical power production and are included as part of sustainable construction efforts. Still other materials are added to improve the ability of a concrete to protect the embedded reinforcement. Often, these additives fill more than one of the aforementioned roles.

Fig. 5 Influence of pH on corrosion rate

Chemical admixtures are often dissolved or dispersed in the mix water. In the United States, materials are typically selected that meet ASTM C 494 or C 1017 (Ref 36, 37). Included are the following.

Accelerators. These are materials that accelerate setting and strength development in concrete. Included are calcium and sodium chloride, triethanolamine, soluble formates, nitrates, nitrites, and thiocyanates. It is noteworthy from a corrosion standpoint that chloride-bearing accelerators are often used during winter concreting. If chloride ions are included in the initial mix, a substantial fraction will become incorporated into the gel phase of the cement paste and may not be as problematic toward corrosion as are free chloride ions dissolved in the pore water. Also, when chloride ions are included in the initial mix, they will be uniformly distributed throughout the matrix. From a corrosion standpoint, uniform chloride content is typically less problematic than situations where the chloride ion content at the reinforcement surface varies at adjacent locations due to variation in depth of concrete cover or to the presence of voids and cracks.

Air-Entraining Agents. These compounds promote formation of small bubbles in the concrete mix. Generally, these entrained air voids are roughly spherical, with diameters ranging from 0.05 to 1.25 mm (0.002 to 0.05 in.). Air entrainment improves the resistance of a concrete to degradation from freeze-thaw cycles, deicers, sulfate attack, and alkali-aggregate reaction. As little as 1.5 vol% of entrained air can provide protection against freeze-thaw weathering. Air entrainment also provides a low-cost method to improve concrete workability. Improving concrete durability will also enhance the ability of the concrete to protect embedded reinforcement. Improving workability will increase the likelihood that the as-constructed concrete is placed properly, without large voids or rock pockets, and hence improves corrosion protection.

Alkali-Reactivity Reducers. While the high pH of concrete provides protection to embedded ferrous reinforcement, that high alkalinity can attack some aggregates. The presence of alkali oxides, such as Na_2O and K_2O , in cement are what elevate the typical concrete pH above 12.4, which is the value that would be expected for a saturated lime solution, $\text{Ca}(\text{OH})_2$. As mentioned, air entrainment can help with alkali reactivity. The hydration processes of some mineral admixtures will reduce the pH. Lithium and barium salts are also employed. Lithium is also used as a humectant in the application of cathodic protection to avoid drying at the anode-concrete interface (see the section "Electrochemical Techniques: Cathodic Protection, Chloride Extraction, and Realkalization" in this article).

Corrosion inhibitors reduce steel corrosion activity. Inhibitors are most commonly introduced to the concrete in the mix water prior to placement. Nitrite salts, particularly calcium

nitrite, are overwhelmingly the most widely used and have the largest body of work reported in the technical literature. Other compounds added to the mix water as corrosion inhibitors include sodium benzoate, phosphates, fluosilicates, and fluoaluminates. Topical inhibitors applied to the concrete surface, such as proprietary amines, may provide some corrosion reduction at crack locations. However, in uncracked concrete, it is likely their transport to the steel surface is too slow to provide significant corrosion inhibition within a reasonable time interval. Manufacturers of inhibitors applied to the surface of corrosion-distressed concrete report effective diffusion coefficients for their products that are almost 1 order of magnitude smaller than those observed for chloride ions in diffusion-resistant latex-modified concrete. With normal concretes, the reported effective topical inhibitor diffusion coefficients indicate that the inhibitors would take over ten times as long to reach the surface of the embedded steel as the chloride ions that initiated the corrosion. If it took 20 years for chloride ions to reach the surface of reinforcing steel embedded in normal concrete, it may take almost 200 years for topically applied inhibitors to reach that same steel surface in sound concrete.

Crack Reducers. Concretes with low or ultralow w/c ratios may suffer from cracking if too much water is lost to the surrounding environment. Such high-performance concretes are less readily penetrated by aggressive ions in the bulk than standard concrete. However, if cracks are present, that benefit may be lost, and the resulting cracked structure may be more prone to corrosion. Proper curing can help to reduce cracking. To provide greater protection with crack-prone concretes or installation conditions, crack reducers may provide benefit. Some crack-reducing admixtures lower the surface tension of the pore water. Small, nonmetallic fibers or microfibers can be added to the mix to provide restraint against cracking.

Permeability Reducers. Polymers can be added to the mix water to reduce permeability and otherwise impede the transport of aggressive ions. The most common of these are latex polymers that are used in latex-modified concretes. Water reducers and mineral admixtures can also reduce permeability.

Retarders. These materials retard the setting time of concrete. Included are sugars, citric acid, tartaric acid, borax, and lignins. From a corrosion standpoint, the chief benefit from using retarders is to secure well-placed and uncracked concrete.

Superplasticizers. These products allow the w/c to be reduced by approximately 12% or more while maintaining a flowable concrete. Reducing water reduces porosity, which, if no cracks or placement-related voids occur, is beneficial in controlling corrosion.

Water Reducers. These products differ from superplasticizers in the degree of water reduction allowed. They reduce the water demand by 5% or more and, like superplasticizers, reduce

the concrete porosity, thereby impeding transport of aggressive ions, oxygen, and reaction products.

Mineral Admixtures. Several mineral admixtures are added to concrete. They can react with water on their own or may require the action of lime derived from the cement. Concretes made with some of these materials can be both stronger and provide greater resistance to corrosion than normal concretes. In addition, the use of some of these materials can remove what would otherwise be a waste stream from industry and provide cement replacement that reduces greenhouse gas emissions.

Cementitious. These materials have hydraulic properties and react with water on their own to form a binder. They can also be blended with portland cement. Included here are blast furnace slags and natural cements.

Pozzolans are siliceous or aluminosilicate compounds that, on their own, do not have cementing properties. The ancient Greeks and Romans knew about natural pozzolans that, when mixed with hydraulic limes, could be used in building (Ref 24). These naturally occurring pozzolans were volcanic materials. Today (2006), pozzolans added to concrete mixes include diatomaceous earths, opaline cherts, calcined clays, and industrial by-products such as fly ash and silica fume. Pozzolans react with calcium hydroxide to form C-S-H.

Pozzolanic and Cementitious. These combine the properties of the first two mineral additives. Included in this group are high-calcium fly ash and blast furnace slag.

Normally Inert Fillers. These materials are added to improve workability or aesthetics and normally provide little benefit to corrosion control. Included here are marble, dolomite, quartz, and granite.

Pozzolan additions can improve the strength of the concrete. Compared to portland cement, pozzolanic reactions proceed slowly. The slow reaction rate can lead to partial filling of capillary pores. The reaction with lime reduces both the hydroxide ion concentration and the ionic strength of the pore solution. Pozzolan additions, particularly silica fume, can produce a capillary pore network with lowered connectivity and increased tortuosity even if the porosity is not markedly reduced. These pore structure changes impede the ability of aggressive ions, such as chloride, from penetrating the high-performance concrete protecting the reinforcing steel. On the other hand, reducing the number of hydroxide ions will lower the pH and thereby lower the threshold chloride ion concentration required to initiate corrosion (Ref 38).

Aggressive Ions

Several aggressive ions are involved in reinforcement corrosion. Most significant in terms of widely observed damage are chlorides, carbon dioxide, and sulfates. These ions can directly destabilize the protective passive oxide layer on

the surface of the steel, or indirectly destabilize that layer by reducing the pore water pH or by attacking the protective concrete and thereby exposing the embedded reinforcement to a more corrosive environment.

Chloride Ions. The passive layer that protects steel in concrete can be destabilized by chloride ions. The threshold at which normal low-alloy steel reinforcement, such as ASTM A706 (Ref 35), will lose passivity depends on pH. Once passivity is lost, the observed corrosion rate is typically most influenced by the permeability of the surrounding concrete to oxygen, the moisture content of the concrete (resistivity), and the ambient temperature. Because of variations in cements, concretes, and local conditions, it is difficult to provide a single, specific chloride ion concentration at the rebar surface that is the global corrosion threshold. Further discussion of pH impact on the influence of chloride ions on reinforcement corrosion is provided in the sections "pH and Corrosion Inhibition" and "Corrosion-Resistant Reinforcement" in this article.

Chloride ion contamination of concrete characteristically follows one or more of four paths. First is contamination from saltwater for reinforced concrete structures exposed to or submerged in marine environments. Second is contamination from chloride ions present in the soils or fill surrounding buried or partially buried structures. Third is from deicers used on highways and bridges. The fourth is from the initial concrete mix, where chloride-bearing accelerators and chloride-contaminated aggregate and/or mix water is used.

For the first three paths, chloride ions enter the concrete at an exposed surface. Depending on the exposure, the chloride ion transport may occur through capillary action, diffusion, or hydraulic effects. For atmospherically exposed concrete, the pores of concrete within 12 to 25 mm (0.5 to 1.0 in.) of the surface may not be saturated with water. It is common for this area to be exposed to alternating periods of wetting and drying. Capillary action is often the dominant transport mechanism in this near-surface area. Deeper into the concrete, the moisture content is generally not as dynamic, so diffusion is normally the dominant transport mechanism. Figure 6 shows a typical profile of chloride ion concentration as a function of depth into atmospherically exposed concrete. Note how capillary action dominates near the surface and, as shown, how washing by the rain can sometimes lead to the highest chloride concentration being a short distance into the concrete rather than at the surface (closest to the chloride ion source).

At depth, diffusion is shown to dominate in Fig. 6. Binding between the chloride ions and cement hydration products can affect the rate of chloride ion transport. That said, observations by numerous works show that after the first 12 to 25 mm (0.5 to 1.0 in.), the chloride profiles fit well with diffusion models. In such efforts, an effective diffusion coefficient is determined,

rather than deriving the actual diffusion coefficient and making allowance for sorption-desorption isotherms.

Static conditions are rarely observed in reinforced-concrete structures. Most efforts to fit profiles of chloride content versus depth from the concrete surface employ Fick's second law:

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} \quad (\text{Eq 1})$$

where C is the chloride ion concentration at some distance x below the concrete or boundary surface at some time t , and D is the diffusion coefficient. In actual practice, the effective diffusion coefficient, D_e , would replace D . Integral solutions to Eq 1 that employ the error function are commonly used to calculate the effective diffusion coefficient, D_e (Ref 39). However, if the calculated diffusion coefficient is used to estimate time to corrosion, models should allow for the fact that the embedded reinforcing steel is a nonporous barrier in a porous matrix and will block diffusional flow. Under such restraint, the chloride ion concentration at the reinforcement surface will increase more rapidly than would be the case with unimpeded diffusion at similar depth in the bulk concrete (Ref 40).

Carbonation. Carbon dioxide is a normal constituent of the air surrounding reinforced-concrete structures. It readily dissolves in water to produce carbonic acid. Rain water typically contains sufficient carbon dioxide to reduce its pH to approximately 5.6 (Ref 41). In some areas, industrial sources or burning of vegetation or agriculture can introduce pollutants such as SO_2 and NO_x , which can reduce the pH even further. In 1997, the average field-measured precipitation pH in the Northeast United States was 4.4 (Ref 42), although wet-deposition pH levels in the Northeast, by 2004 averages, continue to be less than 4.7, with occasional readings dropping to under 4 (Ref 43–46).

Fig. 6 Chloride profile showing capillary effects near the surface and diffusion at depth

Carbonation can influence corrosion of steel reinforcement in several ways. First, carbon dioxide will react with lime, forming insoluble calcium carbonate. This reaction lowers the pore water pH, and that reduction can destabilize passivation. Precipitation of calcium carbonate can self-limit carbonation by effectively blocking pores in the cement. In newer concretes with relatively lower w/c ratios and pores with smaller diameters, carbonation may be limited to just a few millimeters from the concrete surface. In older, high-w/c-ratio concretes with relatively larger pore diameters, calcium carbonate precipitation may not be able to limit subsequent carbonation penetration.

Sulfate Reactions. Trisulfoaluminate (AFt) is formed by the reaction of calcium aluminate with gypsum during early hydration. As with AFm, iron can substitute for aluminum in AFt, also known as ettringite. When the sulfate present during initial hydration is exhausted, further hydration of the aluminates/ferrites converts AFt to AFm. If, after the cement hardening is complete, there is additional reaction with calcium sulfate, AFm can convert back to AFt. An increase in solid volume of approximately 55% attends the conversion of AFm to AFt, a volume change that produces internal stresses that can eventually crack the concrete (Ref 24).

In some areas, the soil or water has a high sulfate concentration. This can cause problems if reinforced concrete abuts such soils and if conditions are favorable to wick water through the overlying concrete. Delayed ettringite formation is another process that can also crack the concrete. The resulting cracks typically provide easier access of corrodants to the reinforcement than sound concrete. If degradation continues, the embedded steel may become directly exposed to the surrounding environment. Increases in corrosion would be expected in both situations.

Compared to submerged or buried exposure, there appears significantly less published literature discussion of aerosol sulfate attack on concrete for atmospheric SO₂ (Ref 47). In boldly exposed areas, it appears that reaction products from SO₂ attack will wash away (Ref 48). However, it has been shown that atmospheric SO₂ can lead to the formation of expansive AFt reaction products and degradation of portland cement paste (Ref 47). The degradation of the cement and concrete can lead to increased embedded reinforcement corrosion.

Electrical Resistivity. Corrosion of steel in concrete often involves discrete anodic and cathodic areas. Given that situation, the ability of a concrete to conduct electricity can play a significant role in regulating the rate of embedded reinforcement corrosion. Table 2 outlines a general relationship between concrete resistivity and the corrosion rate of embedded steel.

Additions of some mineral admixtures, such as silica fume, can produce severalfold increases in the resistivity of the resulting concrete. Reducing the w/c ratio also tends to increase concrete resistivity.

pH and Corrosion Inhibition

Lianfang Li, W.R. Grace & Co.

The corrosion rate of steel in concrete is greatly influenced by the pH of the pore water. The impact of pH on the corrosion process is discussed as follows in some detail.

pH of Concrete Pore Water

Concrete is a porous composite material. Its capillary pores, depending on the environmental moisture condition, are partially or fully filled with a liquid called pore water or pore solution. Interestingly, the pH of concrete pore water most often is not controlled by the calcium hydroxide that is abundant in cement paste (the pH of a saturated solution of Ca(OH)₂ being ~12.6 at room temperature) but by the small quantity of alkalis present in the cement clinker (normally less than 1% by weight of cement). Those alkalis are expressed analytically in terms of the equivalent K₂O and Na₂O but are actually present either as alkali sulfates or alkali-calcium sulfates or in solid solution within certain compounds of the cement. Much of the alkali content, especially that present as alkali sulfate, is readily soluble, following a solubility process that can be expressed as (Ref 50).

where A represents either a sodium (Na) or potassium (K) ion. As a result of the aforementioned reaction, a relatively large amount of Na⁺, K⁺, and OH⁻ ions in the hydrated cement paste is released into the pore water. Figure 7 (Ref 51–60) plots the pore water pH as a function of the cement equivalent Na₂O_e content (Na₂O_e = Na₂O% + 0.66K₂O%). It is obvious that pore water pH increases as cement Na₂O_e% increases. For a cement with Na₂O_e of 0.6%, the limit specified by ASTM C 150 (Ref 61), the expected pore water pH is approximately 13.5. Nevertheless, in addition to cement alkali content, other factors, such as concrete w/c ratio, pozzolanic additions, concrete admixtures, and so on, may also strongly affect pore water pH.

Table 2 Concrete resistivity versus relative corrosion rate

Concrete resistivity, Ω · cm	Relative corrosion rate
<5000	Very high
5000–10,000	High
10,000–20,000	Moderate
>20,000	Low

Source: Ref 49

Chloride Threshold

It is well known that reinforcing steel (rebar) embedded in alkaline, chloride-free concrete exhibits passivity. Under this passive condition, the corrosion rate of steel is negligible. However, chlorides can penetrate into concrete structures that are exposed to deicing salts or a marine environment. When the chlorides at the steel reach a threshold level (often called the chloride threshold), the passive film on the steel surface is disrupted, and active corrosion initiates. The chloride threshold level is commonly presented as a concrete total chloride content, expressed either as a percentage of the weight of cement or concrete, or in kilograms of chlorides per cubic meter of concrete. Nevertheless, a unique value of the chloride threshold for steel in concrete does not exist. Glass and Buenfeld (Ref 62) reported threshold values for carbon steel in the range of 0.17 to 2.5% by weight of cement for actual concrete structures. This large variability can be attributed to many factors, some of which are difficult to identify. Stainless steel reinforcement has substantially higher chloride thresholds (Ref 63, 64).

Effect of pH on Chloride Threshold. The beneficial effect of hydroxide ions in enhancing the resistance to chloride-induced corrosion of carbon steel in alkaline media is widely understood. Based on several published studies, the relationship between the threshold chloride concentration and the pH of alkaline solutions simulating concrete pore water is presented in Fig. 8 (Ref 65–68). It is apparent that the threshold chloride level increased monotonically with the increase of solution pH for all of these cases, irrespective of differences in the solution

Fig. 7 Relationship between pore water pH and cement equivalent, Na₂O_e, content

and carbon steel chemical composition, specimen size and surface finish, testing procedures, and criteria employed to define the threshold. For that reason, the following equation has been proposed to relate the carbon steel threshold chloride level to the solution pH:

$$\text{pH} = n \log[\text{Cl}^-] + K \quad (\text{Eq 3})$$

where n and K are constants, and $[\text{Cl}^-]$ is the carbon steel corrosion threshold chloride concentration. Typical values of n are ~ 0.5 to 1.0 ; however, values much higher than 1.0 have also been reported (Ref 62).

In comparison, studies addressing the relationship between chloride threshold and concrete pore water pH are scarce, partly because of the technical difficulty involved in accurately measuring the pore water pH at the rebar/concrete interface, especially at the time of corrosion initiation. A recent study conducted at Florida Atlantic University (Ref 69) compared the time to corrosion of ASTM G 109-type concrete specimens (Ref 70) using cements of different alkali contents (Fig. 9). The average bulk concrete pore water pH, determined by an ex situ leaching method (Ref 60), was approximately 13.6 for Na_2O_e of 0.97% and 13.2 for Na_2O_e of 0.52%. It can be seen that at $w/c = 0.41$, the time for 50% (two out of four) of the carbon steel specimens to start active corrosion was ~ 1300 days for $\text{pH} = 13.6$ concrete but only approximately 200 days for $\text{pH} = 13.2$ concrete, suggesting the beneficial effect of using high-alkalinity cement.

Applications

In view of the existing evidence, it can be concluded that the chloride threshold of carbon steel rebar in concrete can be elevated by raising

the pH of concrete pore water. In other words, the corrosion initiation time of steel in concrete can be extended by increasing the concrete alkalinity. This can be achieved with minimum cost by either using cements of high alkalinity or externally adding sodium or potassium hydroxide into the mixing water while making the concrete. Approximately 0.5 kg NaOH is needed to raise cement alkalinity by 0.1% for concrete with a cement factor of 400 kg/m^3 . Consider the case where concrete has the following properties: surface chloride content is 5% by weight of cement, the effective diffusion coefficient is $10^{-8} \text{ cm}^2/\text{s}$, and the threshold chloride is 0.5% by weight of cement. If it is assumed that the chloride threshold is doubled when the cement alkalinity is doubled, calculation based on Fick's diffusion law suggests that the corrosion initiation time for carbon steel with a 7.5 cm (3.0 in.) concrete cover will be extended by approximately 20 years as a result of cement alkalinity increase.

The previous estimation does not take into account the possible loss of hydroxide ions due to leaching and/or carbonation. Values of diffusion coefficients for OH^- ions in concrete are scarce, but it is expected to be on the same order of magnitude as that of chlorides for the same type of concrete (Ref 71). Therefore, it is recommended that concrete should be of high quality whenever high-alkali cement is selected for corrosion purposes. As an example, comparing the time-to-corrosion values shown in Fig. 9, concrete with Na_2O_e of 0.97% will outperform that with Na_2O_e of 0.52% at $w/c = 0.41$ but not at $w/c = 0.50$. Another issue related to the use of high-alkali cement is that it increases the risk of concrete expansion due to alkali-silica reaction (ASR) (Ref 72). Widespread occurrence of ASR problems has been reported within the United States (Ref 73). Therefore, before high-alkali cement is used, both fine and coarse

aggregates should be carefully examined for alkali-silica reactivity by following testing procedures as specified in ASTM C 1293 (Ref 74) and/or ASTM C 1260 (Ref 75). Other issues related to the use of high-alkali cement are that it may affect the behavior of concrete admixtures and may also undesirably change the properties of fresh concrete.

Modes of Reinforcement Corrosion

Jack Tinnea, Tinnea & Associates, LLC

Corrosion in concrete is often visualized as a pothole on the deck of a bridge. This is a common highway corrosion failure mode in areas with frequent application of roadway deicers. Spalls and delaminations are also commonly encountered in marine areas. Localized corrosion of steel in concrete can also occur and is often not recognized prior to failure. Spalls, potholes, and delaminations are not a trivial maintenance issue, but they rarely lead to sudden failure. In part, this is due to the fact that they are easily identified, either visually or through sounding techniques. Localized corrosion can lead to catastrophic failure. Localized corrosion of reinforcing steels typically occurs at locations with abrupt changes in the environment surrounding the rebar. This can occur at cracks in the concrete, within posttensioning ducts, at locations where reinforcement exits the concrete, or in areas of high stress.

General Corrosion

When aggressive ions reach the surface of the reinforcement, or if pH is reduced, the steel loses its passive protection and corrodes. The resulting corrosion product occupies greater volume than the parent metal, with variations due to oxidation state and amount of water included in the final product. The corrosion in concrete generally follows a two-step process, shown in Eq 4 and 5:

In oxygenated concrete, the insoluble corrosion products collect at the reinforcement-concrete surface. Hydration also often occurs. As Fig. 10 shows, these hydrated corrosion products occupy significantly more volume than the parent metal. This increase in volume, which is restrained by the presence of the rebar, leads to the development of tensile hoop stresses in the surrounding concrete (Fig. 11a). Concrete is quite strong in compression but has tensile strength that typically runs only 10 to 15% of its compressive strength. Because of this limited

Fig. 8 Relationship between threshold chloride concentration and pH of alkaline solution

Fig. 9 Number of specimens failed as a function of chloride ponding time. w/c , water-cement ratio. Adapted from Ref 66

tensile strength, the concrete cracks to relieve the tensile hoop stresses generated by the expansive corrosion products. The failure mode depends on the strength of the concrete, the depth of concrete cover over the reinforcement, and the spacing between the bars. If there is shallow concrete cover and/or wide spacing of the reinforcement, then vertical cracks form to relieve the corrosion-initiated stress (Fig. 11b). When the reinforcement is more closely spaced or is overlain with a greater depth of concrete cover, the stress-relieving cracks will run through the concrete from bar to bar, forming what is known as a delamination plane (Fig. 11c). Continued general corrosion of the reinforcement, or mechanical action such as from traffic, can dislodge some or all of the delaminated concrete, creating a spall or pothole.

Often, section loss of the steel reinforcement is quite modest until the loss of concrete bond and/or cover. Therefore, the initial problems associated with general corrosion of steel embedded in concrete derive from damage of

the concrete rather than a reduction of reinforcement cross section. Some corrosion-related problems, such as cracking, rust staining, or spalls, are visually obvious. Delaminations, which may not be visually apparent, are typically identified through traditional sounding techniques.

Localized Corrosion

Routine inspections of reinforced concrete structures employ visual inspection and/or sounding techniques to identify reinforcement corrosion. These techniques are good at identifying situations where stress from expansive corrosion products has cracked, delaminated, or spalled the concrete covering the distressed reinforcement. These standard techniques are not similarly effective with situations where localized corrosion has severely damaged reinforcing steel without spalling or delaminating the concrete. Localized corrosion can occur with both conventional reinforcement and prestressing steel. This section addresses localized corrosion involving conventional reinforcement. Localized corrosion is also discussed in the sections "Prestressing Steel" and "Posttensioned Grouted Tendons" in this article.

Cracks in concrete can come from a number of sources other than corrosion. Early loss of moisture can lead to shrinkage cracking. Differential settlement of piling can crack pile caps and beams. The presence of such cracks can disrupt the normal protection afforded by concrete and allow corrosion to occur where the crack intersects the reinforcement. Here, the corrosion activity is localized and involves what are known as macrocells. Other cracklike crevices, transitions, or cold joints can also lead to localized corrosion of embedded reinforcement. Cold joints are the result of common construction practice where the concrete is placed in immediately adjacent areas. Transport of chlorides or other aggressive ions to the steel surface occurs much faster at such locations than in the bulk concrete.

Fig. 10 Comparison of the unit volumes of steel and its corrosion products

Fig. 11 Expansive corrosion products from rebar generate stress in concrete. (a) Tensile hoop stresses develop adjacent to the corroded steel. (b) Wide bar spacing and/or shallow cover favor formation of vertical cracks to relieve the stress created by the expansive corrosion products. (c) Close bar spacing and/or deep cover favor formation of a delamination plane to relieve the stress created by expansive corrosion products.

Several authors have looked at localized/macrocell/crevice corrosion from laboratory, theoretical, and modeling paradigms (Ref 76–81). Localized corrosion of concrete reinforcement has frequently been observed in field situations (Ref 82). Several examples of those situations are discussed as follows.

Localized Corrosion—Adjacent Cathode.

The substructure and supports of a bridge were suffering significant corrosion damage as the result of chloride ion contamination from both deicing salts and the close proximity to the ocean. The continuing chloride ion exposure eventually led to corrosion of the reinforcing steel. In most areas, the chloride ions diffused from the surface to the bar, and corrosion activity was related to depth of cover and proximity to the ocean. In these cases, the damage that resulted was spalling and delamination of the concrete cover.

Figure 12 shows an elevation view of a beam supporting a bridge where differential settlement had generated a narrow (<0.5 mm, or 0.02 in., wide) crack. It appears that the concrete had cracked early in the service life of the bridge. The bridge is located in an area with significant tidal variation (>3 m, or 10 ft). At extreme high tides or during storms, the crack would be wetted with saltwater splash. The narrow crack wicked chlorides rapidly to the level of the reinforcement. Although there was a rust stain on the concrete surface, sounding the concrete with a hammer did not indicate a problem, that is, a hollow sound indicating delamination, so initially no repairs were scheduled. The rust staining was attributed to a tie wire or other trivial surface artifact. Measurements of the corrosion potential of embedded steel in the vicinity of the crack showed rapid change of potential (>150 mV) within a short distance (<150 mm, or 6 in.). An abrupt change in the corrosion potential of reinforcement in the vicinity of cracks, cold joints, or even in apparently sound concrete is often indicative of severe corrosion of embedded reinforcing steel. The area was excavated, and all of the lower bars in the pile cap supporting the deck, and shown in Fig. 12, were severely corroded (>50% loss of cross section) or had fully failed. Figure 13 shows a closeup of one of the bars. Figure 14 shows a similar failure of a stirrup at a location where early cracking of the beam occurred. All the stirrups on one side

Fig. 12 Elevation view of cracked beam. Localized corrosion cut all the rebars crossing the crack, including those at the beam bottom.

Fig. 13 Closeup of reinforcing bar that suffered full-section failure. Approximately three-fourths of this bar was fully corroded, with the remaining one-fourth cracked.

Fig. 14 Closeup of a fully failed pile cap stirrup. Note that immediately above the severely corroded area, the bar shows no sign of corrosion. The upper area was in a passive condition and served as the cathode for corrosion of the area just below. Close interval mapping of reinforcement corrosion potential can identify these situations.

of the beam suffered >50% section loss due to localized corrosion.

In both cases, the pile cap and the beam stirrups, the cracks had high average times of wetness. This fact kept the chloride ions available for corrosion activation, iron transport, and hydrolysis. As a consequence, soluble corrosion ferrous ions (Eq 4) were transported from the steel surface. A schematic of the corrosion process is shown in Fig. 15. Here, iron from the steel reinforcement goes into solution as Fe^{2+} . The ferrous ion is able to move away from the surface of the parent steel as a soluble hydroxide or as a chloride complex. Completion of the oxidation process, and formation of voluminous red rust corrosion products (Eq 5), occurs either at the concrete surface (the crack opening) or in concrete pores ($\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$). The differential in chloride concentrations allows steel exposed to the crack to be the anode and metal exposed to the adjacent chloride-free concrete to be the cathode.

Being able to transport reduced iron, or its chloride complexes, from the corroding surface allows entrained air and voids in the concrete to provide locations that can accommodate the formation of relatively large red rust hydrated corrosion product. This dispersal of the corrosion products avoids developing tensile hoop stresses at the reinforcement surface and subsequent cracking, spalling, and delamination of the concrete.

In both of the cases shown in Fig. 14 and 15, traditional sounding techniques did not indicate a corrosion problem. Close-interval (150 mm, or 6 in.) measurement of the embedded reinforcement corrosion potential clearly indicated abrupt changes in potential and provided a good indicator that localized corrosion was present.

Localized Corrosion—Remote Cathode. A situation similar to the bridge cap beam can

occur on retaining walls and tunnels. Figure 16 shows a localized corrosion failure that occurred at a cold joint in a retaining wall with a double mat of reinforcement. One face of the retaining wall was exposed to chloride-contaminated fill, while the other face was exposed to the atmosphere. Chloride ions migrated along the cold joint to the layer of reinforcement closest to the fill and became the anode in the distinct macrocell. The cathode was the mat of reinforcing steel that was closest to the atmospherically exposed surface and had a higher oxygen concentration.

A concrete construction cold joint may be thought of as a very narrow crack. Although it is a narrow crack, it is a much less encumbered chemical transport path than is the much more tortuous passageway through the cement pore network provided by an equal thickness of bulk concrete. Generally, it is desirable to avoid construction joints in areas where corrosion accelerators are present (Ref 83). However, budgets and other considerations may result in the presence of construction joints where corrosive materials, such as chloride- or high-sulfate-bearing soils, can enter the joint.

In cases of tunnels or retaining walls, the cathode can be at a distance from the anode in a macrocell configuration. With both adjacent and remote cathode configurations, time of wetness at the anode significantly affects the observed corrosion. In the confined area, particularly cracks or cold joints, aggressive ions can build up, and hydrolysis reactions can produce a significant drop in pH. With a remote cathode, the effective cathode area is much larger than the anode, and oxygen transport to that area may play less of a role in controlling the corrosion rate than concrete resistivity. The resistivity of the concrete can attenuate the effective cathode, and a relatively low-resistivity concrete can, under comparable circumstances,

Fig. 15 Schematic of localized corrosion with adjacent cathode

Fig. 16 Localized full-section corrosion failure with remote cathode

provide a larger cathode than a high-resistivity concrete.

Prestressing Steel

William H. Hartt, Florida Atlantic University

Prestressed concrete bridge construction uses high-strength steel as either solid bars or, more commonly, seven-wire spirally wound strand. The underlying principle is that tensile forces in the steel, which are applied either before or after concrete placement and setting, depending on the prestressing method, impart compressive stresses to the concrete upon force release. Presence of a compressive stress state in the concrete, which is relatively brittle, enhances tensile load-bearing capacity. Because of reduced material cost, structural efficiency, and a more streamlined appearance, more than 50% of all new bridge construction now uses prestressing. Additional insight into the principles of prestressed concrete construction can be obtained from standard texts in the field (Ref 84).

Types of Prestressed Concrete Construction

There are two general categories of prestressed concrete construction: pre- and post-tensioned. For the first (pretensioned), the steel is tensioned prior to concrete pouring, with the steel ends being released subsequent to concrete setting. As such, the prestressing is bonded directly to the concrete. Production of pretensioned concrete takes place at a central fabrication yard and involves standardized components such as pilings and I-beams that are subsequently transported to the jobsite. Posttensioning, on the other hand, requires that the steel is contained within plastic ducts that are positioned within the concrete formwork at the construction site. (Historically, metallic and even paper ducts have been employed in posttensioned construction; however, these have been discontinued because of corrosion in the former case and inadequate protection from inwardly migrating aggressive species in the latter.) These ducts are tensioned and anchored subsequent to concrete setting. As such, it is the duct and not the posttensioned steel that is bonded to the concrete. Ducts are grouted subsequent to tensioning to provide added corrosion protection to the strand. Earlier bridge construction methods employed an inhibited grease.

Within the past two decades, segmental post-tensioning, which is a modification to conventional posttensioning, has increasingly been employed. Here, multiple strands are contained

within a duct, and the system is extended through multiple precast hollow roadway or column concrete sections. Upon tensioning, the segments are squeezed together, providing structural integrity to the assembly.

Categories of Prestressing Steel

Prestressing steel strand normally conforms to ASTM standard specification A 416/A 416M (Ref 85). This specification covers two types and two grades of uncoated strand. The types are normal and low relaxation, where only thermal treatment (stress relief) is employed for the former and continuous thermal-mechanical treatment for the latter. Low-relaxation strand, for which a maximum relaxation loss of 2.5% is specified during 1000 h at a load of 70% of the specified minimum breaking strength, is the industry standard, because any relaxation after tensioning reduces compressive stress in the concrete. The grades are grade 1725 (250) and grade 1860 (270), where the numerical designation is the minimum ultimate tensile strength in Système Internationale (SI), 1725 and 1860 MPa and customary units (250 and 270 ksi). No upper strength limit is specified; while there are no reports of this being a problem for strand, excessive strength has led to premature failures of prestressed concrete cylinder pipe, which is wire-wound (Ref 86). (The failures were attributed to dynamic strain aging. This was apparent as wire splitting, which led to loss of prestress and pipe rupture and reflected the fact that brittle fracture and environmental cracking tendency generally increase with increasing strength.) Strands must necessarily be of relatively high strength and support high loads if meaningful compressive stresses are to be imparted to the concrete, because cross-sectional area for the strand is small compared to that of the concrete.

The ASTM A 416/A 416M specification (Ref 85) requires that the wire from which strand is fabricated be drawn carbon steel and that the final product (strand) possess specified dimensions and a requisite minimum strength. As such, steel composition is not addressed; however, attainment of the required mechanical properties using a carbon steel is most reliably achieved with a near-eutectoid composition (0.77 wt% C). Quenched and tempered steel is precluded because of its relatively brittle nature and susceptibility to environmental cracking.

A recent specification, ASTM A 882, has been published for filled, fusion-bonded, epoxy-coated prestressing strand (Ref 87) that otherwise conforms to ASTM A 416. The coating is applied by the electrostatic deposition method and is provided with or without embedded grit to enhance the bond to concrete. Because of the inherent viscoelastic nature of epoxies, a maximum relaxation loss of 6.5% is allowed, compared to 2.5% for the uncoated (bare) strand. Caution must be exercised, because elevated temperatures could cause coating softening and

result in loss of prestress transfer. The specification requires the epoxy to be capable of reaching 66 °C (150 °F) without reducing transfer.

Performance of Prestressing Steel in Concrete Highway Structures

Corrosion of reinforcing steel, both conventional and prestressed, as a consequence of either marine exposure or application in northern climates of chloride-based deicing salts (or both) has evolved to become a formidable technical, societal, and economic problem in North America and elsewhere. Such damage is more critical for prestressing than conventional reinforcement, because higher stresses are present in the former. Consequently, a relatively small amount of corrosion on a single wire can cause its fracture. This then transfers load to the remaining six wires of the strand, which, in combination with further corrosion, can lead to fracture of the strand and load transference to adjacent strands.

Corrosion of pretensioned strand in concrete normally proceeds by the same mechanism as for conventional reinforcement and involves progressive migration of chlorides into the concrete until a critical concentration is reached at the steel depth. At this time, passivity is compromised, and corrosion initiates. This is followed by accumulation of solid corrosion products about the steel, which leads to concrete cracking and spalling. As for conventionally reinforced steel, methods for corrosion assessment, such as measurement of potential and polarization resistance, apply. In the case of posttensioning, corrosion damage results from water intrusion into the duct or end anchorage, irrespective of the presence of chlorides. Such intrusion can occur during construction when the posttensioning is exposed or subsequently as a consequence of leakage. For this reason, sound grouting materials and practices and protection of end anchorages are critical. Tendon failures on segmental bridges as a consequence of strand corrosion from excessive bleed water have recently been reported (Ref 88). This, in turn, has led to specification of thixotropic grouts. A point of concern for posttensioning is that the conventional corrosion assessment methods for pretensioning are not applicable, because the strands are electrically shielded by the duct. Techniques based on impulse radar, high-energy linear accelerator, impact echo (Ref 89, 90), magnetic flux leakage (Ref 91), and vibration testing (Ref 90) (the latter is applicable to external tendons only) can be employed for situations where access is restricted by expense or design.

The possibility of hydrogen embrittlement as a consequence of corrosion is also a point of concern. Hydrogen ions are produced by the reaction:

with subsequent formation of adsorbed atomic hydrogen, H_{ads} , according to the reduction reaction:

Alternatively, in deaerated regions or with excessive cathodic polarization, the reaction:

occurs. The H_{ads} product has two reaction paths available:

or

where H_{dis} is hydrogen dissolved in the steel that contributes to embrittlement.

Cathodic protection (CP) is the only proven long-term service method controlling ongoing corrosion of steel in chloride-contaminated concrete. Because of the relatively high resistivity of concrete and the need for a high driving voltage, most CP systems for reinforcement have been of the impressed-current type. However, concern with overprotection and hydrogen generation (Eq 8) in some areas has largely precluded application of this technology to prestressed concrete bridge structures. With this in mind, a recent state-of-the-art report (Ref 92) has addressed protection criteria for prestressed concrete. Galvanic anode (sacrificial) CP has been successfully employed in warm marine applications, but performance is often insufficient in colder, drier climates. Improved anodes (Ref 93) and application of humectants (Ref 94) are being developed to overcome this poor performance.

Posttensioned Grouted Tendons

Alberto A. Sagüés,
University of South Florida

Posttensioned (PT) tendons are placed through a concrete structure after the concrete is hardened, and then stretched to provide compressive forces that hold the structure together. The ends of the cables are held by anchorages (Fig. 17) that are usually embedded in the concrete. The anchorages typically have a wedge plate with wedges that hold the stressed cables in place after tension is applied by a hydraulic jack. A tendon usually has multiple (often 19) strands. Each strand is typically made of seven 5 mm (0.2 in.) diameter wires, with a central straight wire and the remaining six in a helical pattern around the center wire. The strands themselves run nearly parallel to each other over most of the length of the tendon, with little or no braiding effect. The wires are usually made of a near-eutectoid-

composition low-alloy carbon steel, heat treated and cold worked (later stress relieved) to achieve a very high tensile strength (1.86 GPa, or 270 ksi). The microstructure resembles fine pearlite, with grains very elongated in the drawing direction. The wire surface usually has only a thin mill scale. Anchorage bodies are commonly made of cast iron, while the wedge plate and wedges are typically carbon steel.

Tendons are placed in ducts that may be embedded in concrete (internal tendons) or have portions of the tendon in air space between concrete components (external tendons). Ducts can be metallic (galvanized, corrugated, or straight pipe), as is often the case for internal tendons, or polymeric (such as high-density polyethylene (HDPE), commonly used for external tendons). The ducts and anchorages can be filled with cementitious grout or grease. In case of failure of one or more strands, the grout serves a mechanical function by frictionally transferring load to the remaining unbroken strands or the anchorage, as long as there is a sufficient transfer length. Such mechanical transfer is not effective in the case of grease-filled tendons. Staehle and Little (Ref 95) documented corrosion development by fungal action in a greased PT assembly. The focus of this section is on corrosion of PT grouted tendons, in particular related to recent tendon failures in bridge applications.

The tendons concerned are critical structural components carrying forces often greater than 10^6 N (225,000 lbf), and failure of more than one or two nearby tendons in a structure can be catastrophic. Given the intrinsically low corrosion resistance of the tendon steel, control of its immediate environment is essential. Hardened cementitious grout should have high pore water pH (typically >13), very low chloride content (e.g., <100 ppm of the grout mass) to ensure stable steel passivity (Ref 67), and high electric resistivity (e.g., well above $10 \text{ k}\Omega \cdot \text{cm}$) to minimize adverse galvanic coupling should active corrosion develop.

Instances of PT strand corrosion in segmental bridges took place in the 1980s in Europe (Ref 96), leading to an application moratorium in the United Kingdom for a time. Corrosion of PT strands has received renewed attention since a series of failed tendon incidents occurred in the late 1990s in Florida. Those occurred around the (then) 18 year old Niles Channel Bridge in the Florida Keys (Ref 97, 98), the 7 year old Mid Bay

Fig. 17 Idealized schematic of a typical anchorage system. Only three strands shown for clarity. Anchor, wedge plate, and wedges are ferrous alloys.

Bridge in the Western panhandle (Ref 99), and the 15 year old Sunshine Skyway Bridge over Tampa Bay (Ref 100). In each of these bridges, the observed damage consisted of one completely cut tendon plus one to several partially detensioned tendons. The completely cut tendons had failed in the anchorage region following severe corrosion of many of the strands, as illustrated in Fig. 18.

Mechanical failure appeared to be the result of simple overload of locally reduced cross section, usually in the form of generalized corrosion along several centimeters of strand length, with occasional pitting. In the partially detensioned tendons, severe corrosion and mechanical failure had affected some but not all of the strands. In one instance, the area of severe corrosion was approximately 2 to 3 m (7 to 10 ft) away from the anchorage. All cases of severe corrosion were associated with large void areas that should have been filled with grout. Significant chloride contamination of the remaining grout was observed at some of the corroded regions. In many cases, the affected anchorages were at bridge expansion joints or underneath horizontal surfaces, where salt and moisture availability was significant. Additionally, HDPE duct cracks were commonly encountered in the Mid Bay Bridge. Corrosion was not unique to any particular anchorage manufacturer.

The available evidence suggests that the key deterioration factor in the Florida incidents was the formation of large grout voids at or near the anchorages. The most likely cause of voids is the development of large amounts of bleed water during the grouting process at the time of construction of the affected bridges (Ref 101, 102). Bleeding is assisted by wicking of water along the strands and vibration resulting from the grout-pumping operations. The bleed water may be subsequently reabsorbed into the grout or lost by evaporation through incomplete anchorage sealing that may result from deficiencies at the pourback on the wedge plate or elsewhere (e.g., duct connections or duct cracking). Thus, some of the steel is not in contact with the bulk of the protective highly alkaline grout that is intended to promote passivity of the steel surface. The region where the steel emerges from the grout-void interface is particularly vulnerable because

Fig. 18 Failed strands from corrosion in grout void area of an anchorage. Courtesy of Florida Department of Transportation

of a combination of detrimental factors. The pH of the grout pore water there could be lowered by carbonation from atmospheric carbon dioxide. At the same time, evaporative chloride ion enrichment may occur, elevating the chloride content (that could be either the small native content of the grout or some larger amount from external contamination) to a level sufficient to cause passivity breakdown at the local pH and potential conditions. After initiation, further corrosion may be accelerated through galvanic coupling of the relatively small active region with a larger passive surface consisting of the rest of the strand assembly in the grout, plus other metallic parts of the anchorage. In the absence of free bleed water, the extent of the corrosion macrocell action is expected to depend on the polarization characteristics of the anodic and cathodic zones and on the resistivity of the intervening hardened grout.

The aforementioned corrosion scenario has been supported by preliminary laboratory experiments that showed lowered pH and enhanced chloride content (as well as increased grout porosity) at the grout-void interface of a model anchorage assembly (Ref 102). Adverse galvanic coupling with the anchorage and severe active corrosion were documented for that region. The local corrosion rates were on the order of $10^2 \mu\text{A}/\text{cm}^2$, sufficient to cause mechanical failure of at least some wires after short periods, for example, 1 year. Fast corrosion failure of an experimental anchorage has been reported elsewhere (Ref 103). Additional evidence of corrosion while bleed water was still present is detailed in Ref 104. These cases suggest that some of the damage in the affected bridges may have been quite advanced early in the service life of the affected bridges. Newly introduced low-bleed, high-w/c-ratio grouts (Ref 105, 106) have shown encouraging performance in preventing void formation. Significant self-desiccation appears to take place during extended curing of those grouts, as indicated by terminal electric resistivity and internal relative humidity values $>10^4 \Omega \cdot \text{cm}$ and $<80\%$, respectively (Ref 107). Active corrosion is difficult to sustain in cementitious media under those conditions. However, initial modeling calculations indicate that if a small active anodic zone still existed at the grout-void interface, macrocell coupling with extended cathodes elsewhere on the strand and anchorage body could still be substantial at moderate-to-high resistivities, given enough oxygen availability (Ref 107–109).

Early detection of PT corrosion is highly desirable but not easy. Even in the case of essentially external tendons, much of the damage can happen within anchorage areas that are normally encased in thick concrete bulkheads. Direct inspection of anchorages can be made by removing the mortar pourback covering the wedge plate and inserting a boroscope through an unused wedge seat into grout voids, should those become observable. This procedure was used extensively to assess the condition of the

surface strands exposed at voids (Ref 99) in the Mid Bay Bridge. Open-circuit potential measurements using a reference electrode inserted in the assembly to reveal possible active corrosion, as in ASTM C 876 (Ref 110), are feasible and have been used routinely as well. However, the corrosion may have existed early in the life of the structure, and potentials at the time of inspection may be in the passive range, even if the damage was extensive earlier. A similar situation exists for polarization resistance or electrochemical impedance measurements. Continuing electrochemical testing (either by static potential, electrochemical noise, or transient polarization methods) is, in principle, feasible but has not yet been practically implemented. Nondestructive magnetic assessment of the external portion of tendons using a traveling probe has been conducted routinely in several bridges, but the method is limited to regions away from the anchorage, where severe damage is less common (Ref 111). Radiographic methods to evaluate anchorages are feasible, to some extent, but generally slow and expensive. Pulse-echo and related ultrasonic assessment, with acoustic excitation at individual strands exposed at the back of the wedge plate, has been attempted but with limited success. Macroscopic acoustic methods exist based on monitoring to record individual strand breakages (Ref 111, 112); however, these procedures require continuous data acquisition at fast rates and over the entire service life of the structure, and a dedicated data processing service with consequent cost issues.

Electrical resistance measurements of tendons (end-to-end or at intermediate positions, using a traveling potential contact) have been performed in external tendons, using highly sensitive electric bridge circuitry to reveal partial discontinuities at wire breaks, including those in the hidden anchorage area (Ref 98). This method has shown promising results, but it is time-consuming and requires disruptive placement of electric contacts through the tendon duct. Vibration testing (using either natural traffic excitation or controlled impact) has been used extensively in recent years to determine the state of tension of external tendons. Tendons showing unusually low tension (or unusual disparities of tension at opposite ends of the same tendon) are suspected of having experienced breakage of one or more strands somewhere along the tendon, including end anchorages. The procedure is relatively inexpensive and fast and has been used together with boroscope examination of anchorages to identify suspect units in bridges with large tendon inventories (Ref 98, 113). Vibration tests have correctly identified some tendons with damage in progress, but not always. Corrosion can still remain undetected if grout and friction permit efficient transfer of force to adjacent strands, so that the tension at the external portion remains essentially unaffected. Due to the shortcomings of individual inspection methods, a reasonable chance of detecting PT corrosion before complete tendon failure

requires a combination of various techniques at present.

The corrosion incidents in Florida highlight the sensitivity of PT systems to design weaknesses and construction quality. As a result of those incidents, the Florida Department of Transportation has developed an extensive set of new design and quality guidelines aimed at control of PT corrosion in new structures (Ref 114). Those guidelines include the use of low-bleed grouts, grout-pumping procedures for prevention of voids, redundant anchorage capping and improved polymer ducts for isolation from the external environment to prevent moisture ingress, and construction detailing to avoid chloride contamination of regions around anchorages.

Related structural components experience some corrosion modalities that are common with those of grouted tendons. A detailed treatment of cable corrosion in bridges and other structures is found in Ref 115. Issues on corrosion of prestressing steel are summarized in Ref 116.

Corrosion Inspection

Jack Tinnea, Tinnea & Associates, LLC

Corrosion inspection of bridges and highways requires an understanding of both civil and corrosion engineering. In the United States, the ownership of bridges is diverse and includes private and government agencies, including groups from local, state, and federal government. Although there is local variation in inspection requirements, at the top of the inspection protocol are the National Bridge Inspection Standards. Inspection typically defers to the American Association of State and Highway Transportation Officials' (AASHTO) *Manual for Condition Evaluation of Bridges* (Ref 117). For structures that include underwater reinforced-concrete components, the book *Underwater Investigations—Standard Practice Manual* (Ref 118) is very helpful. An excellent guide written in Spanish is also available (Ref 119). NACE International is working on a recommended practice for conducting corrosion inspections of reinforced-concrete structures that should be completed in 2006.

Corrosion Condition Surveys

Corrosion condition surveys are a part of standard bridge and highway inspections that should be conducted at regular intervals. Bridges are typically inspected in 24 month intervals and underwater inspections in 60 month intervals. If premature deterioration is suspected, then the time interval may be shortened as required. In some cases, it may be necessary to employ

sophisticated equipment and techniques to determine the extent of damage. This discussion highlights corrosion issues that may be present in bridges being inspected. It is important to recognize that proper bridge inspection should be performed by qualified individuals with specific training and professional licensing. As required, corrosion specialists may be involved to assist in defining corrosion conditions and to provide input on appropriate action to resolve corrosion problems.

Bridges and highways include a number of elements that may encounter corrosion problems. Included are:

- Bridge decks and reinforced slabs
- Superstructure and substructure members
- Deck joint elements
- Bearings
- Railings
- Culverts

Metal elements can be painted, galvanized, thermal sprayed, or left bare, such as weathering steels. Reinforced concrete can include reinforcement that is conventional or prestressed. The reinforcement can be bare, galvanized, epoxy coated, cathodically protected, or fabricated from corrosion-resistant materials.

Elements to consider in a corrosion inspection of reinforced-concrete highways and bridge members include:

- Assessment of concrete strength and condition
- Cover thickness survey
- Visual inspection techniques for cracks and rust staining
- Delamination survey

- Corrosion potential measurements and mapping
- Concrete resistivity determination
- Chloride profile determination
- Carbonation testing
- Corrosion rate monitoring
- Other advanced techniques

Elements to consider in a corrosion inspection of the structural steel elements of a bridge include:

- Visual inspection techniques for rust staining
- Assessment of coating condition
- If present, identification of crevice corrosion on bolted joints or hinges

There is such a very wide range of bridge types, structures, and environments that it is not possible to provide a single strategy. However, in all cases, it is important that individuals with extensive experience in the area of highway-related corrosion review the corrosion survey findings and that they discuss the implications of the results with an appropriate structural engineer.

Assessment of Concrete Quality and Cover

An accurate assessment of the concrete of a reinforced-concrete structure and the typical depth by which it covers the reinforcement can provide important information for a corrosion inspection. Generally speaking, good-quality concrete allows slower diffusion of aggressive ions and also slower degradation if corrosion initiates. Figure 19 shows how the quality of

concrete can influence the corrosion threshold (Ref 120). Here, two curves are shown that delineate good-quality and bad-quality concrete. Most concretes encountered in field situations fall between these two curves. As can be seen, the chloride content threshold required to initiate corrosion varies both by concrete quality and the humidity of the local environment or micro-environment.

Figure 20 shows a variation on what has become the classical representation of cumulative corrosion damage versus time (Ref 121). A good understanding of this behavior is necessary when relating the findings of a corrosion inspection to the expected service life of a structure. The corrosion initiation phase is the time before the onset of significant reinforcement corrosion. This is the period when aggressive ions, such as chlorides, penetrate the concrete cover and reach the level of the reinforcement, or when the carbonation front reaches the embedded metal surface. This period is shown ending at point t_0 , when conditions reach the local corrosion threshold. Note that there may be some initial cracking early in the corrosion initiation phase. These may derive from processes other than corrosion, such as drying shrinkage. If such cracks reach the steel surface, their presence may greatly compress the corrosion initiation phase.

The next time interval shown in Fig. 20 is that of the corrosion propagation phase. Note that after a relatively short nonlinear period immediately after t_0 , there is a relatively linear increase in damage with time during most of the remaining propagation phase. Shortly before the point noted as "Corrosion failure," the rate of corrosion damage typically shows a dramatic increase. "Corrosion failure" is assumed to be the point of maximum allowable corrosion damage and is also noted by the time t_F . The point of corrosion failure, t_F , would be the end of the service life with no remediation or repairs.

If maintenance is applied to extend the life of the structure, that maintenance could come either before or after the onset of corrosion, t_0 . The point t_{RM} and the damage-versus-time plot that follows reflect reactive maintenance, or that

Fig. 19 Impact of concrete quality on chloride content (wt% to cement) corrosion threshold. RH, relative humidity

Fig. 20 Plot of cumulative damage versus time, with several maintenance options

occurring after the onset of significant corrosion. The point t_{PM} and the following plot reflect proactive maintenance. For example, if chloride ion contamination was the defining corrosion issue for a structure, electrochemical chloride extraction could be applied either before or after the onset of significant corrosion activity and damage. Proactive maintenance typically will minimize incurred damage.

Visual Inspection and Delamination Survey

A visual inspection can help to identify problem areas. Sounding techniques can help to identify areas of cracked concrete that have not yet spalled. ASTM method D 4580 covers measurement of delaminations by sounding. Visual inspection and sounding techniques can help the corrosion inspection team in directing their efforts. These techniques should be thought of as complementary, with sounding being able to help in identifying distress that is not immediately apparent visually. However, if there are visual indications of corrosion, for example, rust staining, but sounding does not indicate delamination, further examination should be considered. For example, potential mapping may help to clearly understand the situation. If the cracks that make up the delamination are filled with water, sounding techniques may not indicate a problem. Likewise, if the rust stains are indicative of localized corrosion, there may be severe reinforcement section loss but without development of tensile hoop stresses that crack and spall the concrete. In both of these cases, potential mapping may help to more clearly define the situation.

Reinforcement Potentials

Corrosion potentials are employed in evaluating the corrosion condition of a reinforced structure. Figure 21 shows the standard setup used to obtain corrosion potentials of reinforcement in concrete. Figure 21(a) shows a passive

noncorroding situation. Figure 21(b) shows chloride ion contamination reaching the level of the reinforcement, and the reading indicates that corrosion is occurring. The absolute value of these potentials can provide some guidance on corrosion activity. Table 3 presents guidelines from ASTM standard test method C 876 on interpreting corrosion potentials of steel in concrete (Ref 110).

In addition to absolute corrosion potentials, patterns seen in maps of close-interval potential readings can reflect structural activity or localized corrosion. A close-interval map obtained on the surface of a floor beam is shown in Fig. 22 (Ref 122). Note that the most negative readings, that is, the values indicative of corrosion, correspond to areas where bending moment, fatigue, or load transfer are occurring. The potential map that appears at the bottom of Fig. 22 essentially reflects a stress map of the floor beam.

Oxygen is a cathodic depolarizer. For reinforcement potentials, this means that if other conditions such as pH, chloride content, and concrete quality remain consistent, then the availability of oxygen will affect the measured potential. In dry concrete, where oxygen has relatively easy access to the steel surface, potentials will be more positive than if that same specimen concrete was fully saturated with water. Full saturation impedes oxygen transport to the steel surface, and, in time, reduced oxygen at the metal surface will shift corrosion potential readings in a negative direction. In tunnels, for example, it is not unusual to encounter readings that ASTM C 876 would indicate reflect a high corrosion probability. However, these relatively negative readings really reflect an absence of oxygen. Figure 23(a) and (b) show how it may be necessary to look at the variation in potential in addition to its absolute value (Ref 123). In Fig. 23(a), the three-dimensional (3-D) map shows readings from a marine piling that was submerged almost all of the time. At this location, sea life and microbes on the pile surface consume essentially all available oxygen. The resulting corrosion potentials, although fairly negative, also show little variation. This is a situation that is characteristic of low oxygen/no

oxygen available at the steel surface. The corrosion rate for reinforcing steel in such anaerobic conditions is low, and no corrosion activity or damage was noted in this area of the pile. In Fig. 23(b), the corrosion potentials are much more electropositive, but the 3-D map shows an abrupt change in potential at approximately the 61 cm (24 in.) location on the length axis. Note in the grid above the 3-D map that the area with the negative potentials is coincident with an area with delaminated concrete cover, indicating problems with reinforcement corrosion. If localized corrosion is suspected, it is helpful to excavate a worst-case area for visual inspection.

Concrete Resistivity

Electrical resistance plays a major role in corrosion in concrete and in the effectiveness of cathodic protection (CP) if applied in a restoration. The corrosion rate of a corrosion macrocell, or output of a CP system, follows Ohm's law, $E = IR$, where E is output voltage, I is CP current, and R is the total circuit resistance. The total circuit resistance comes from several sources, including:

- Concrete resistivity
- Concrete-CP anode interfacial resistance
- Concrete-reinforcement interfacial resistance
- Resistance between individual elements of the reinforcement matrix

Concrete resistivity, the measure of unit resistance of the concrete, is dynamic and plays a large role in the operation of CP systems applied to reinforced-concrete structures. In addition to providing a means of estimating CP current output, concrete resistivity can provide information on the following properties:

- The amount of moisture contained in the cement pores
- The size and distribution of the cement pores (and microcracks)
- How complex a path the pores follow (tortuosity)
- How well the pores are interconnected

Concrete resistivity is strongly influenced by the quality of the concrete and hence reflects the concrete w/c ratio, cement content, use of mineral and other admixtures, and curing conditions.

Of all the factors that affect concrete resistivity, moisture influence is greatest. A high w/c

Fig. 21 Schematic showing the layout for potential testing. (a) The meter reading of -0.100 V to a copper-copper sulfate electrode reflects a noncorroding condition. (b) The -0.400 V to a copper-copper sulfate electrode reading reflects a corroding condition.

Table 3 Interpretation of corrosion potential data

Reinforcement potential (CSE), V	Corrosion condition
> -0.20	$> 90\%$ probability of no corrosion
-0.20 to -0.35	Corrosion activity uncertain
< -0.35	$> 90\%$ probability of corrosion

CSE, copper-copper sulfate electrode

Fig. 22 Close-interval potential map showing the effect of loading and load-transfer fatigue on floor beam reinforcement corrosion

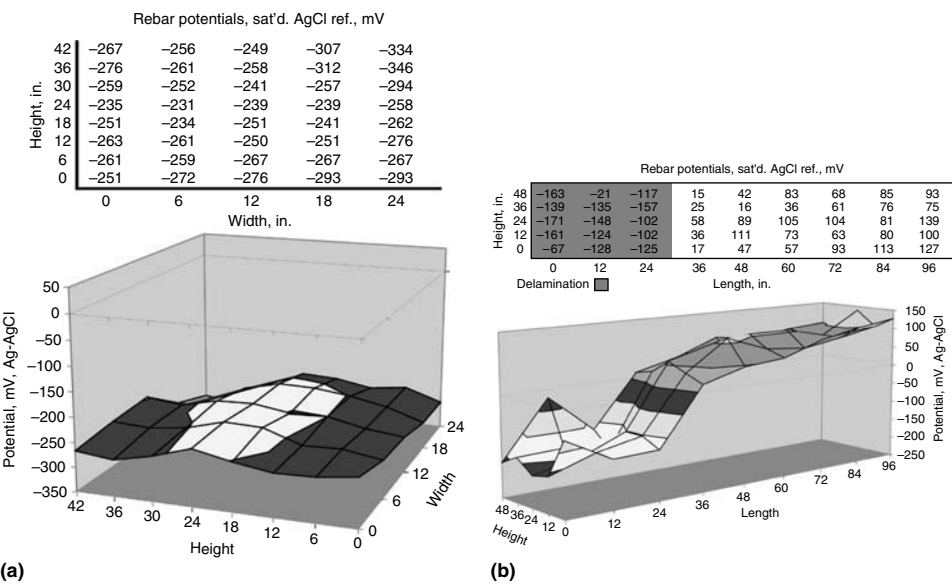

Fig. 23 Map of potential variations. (a) Low potential variation with relatively negative potentials indicates very low oxygen availability and little corrosion. (b) Abrupt variation in potential indicates corrosion activity.

ratio means more and larger pores and a less tortuous path (Ref 31). This, in turn, affords additional room to hold water and generally produces lower resistivities than are observed with low-w/c-ratio mixes. The presence of mobile ions, such as chloride, may have some direct impact on concrete resistivity by increasing the electrical conductivity of the pore water. However, chloride ions also tend to be hygroscopic and improve the capacity of concrete to retain moisture (Ref 124, 125). If other factors are held constant, the addition of chloride ions will reduce hydroxide ion concentration. Given that the specific ion equivalent mobility and conductivity of the replaced hydroxide ion are approximately twice that of the chloride ion, from a conductivity standpoint alone, chloride ion additions would be expected to increase concrete resistivity, not decrease it. Because that is not the generally observed situation, it seems reasonable to expect that hygroscopic action, which increases water retention, more greatly influences measured resistivity than changes in pore water conductivity that result from the addition of chloride.

Electrical resistivity of the concrete is strongly influenced by cement pore structure. It provides a good measure of the permeability and corrosion condition of a concrete. Several authors have examined concrete resistivity as a measure of the corrosion condition (Ref 126–128). Table 4 provides an overview of those suggested relationships.

It must be understood, however, that simply because a concrete resistivity is low does not mean that the reinforcement corrosion rate is high. Following Feliu's (Ref 127) rating system, a low concrete resistivity simply means that concrete resistivity does not seriously impede corrosion. For example, take a situation where reinforcement is embedded in uncontaminated concrete, and the cement pores are fully saturated with water. Because of the moisture content, the concrete resistivity will be low. Further, because of limited oxygen availability, the potential of the reinforcement will be shifted in a negative direction, perhaps to indeterminate values. This does not reflect a corrosive environment but is a reflection of environmental conditions. If this concrete dries, its resistivity will increase, and the potential of the embedded reinforcement will become more positive because of cathodic depolarization from increased oxygen availability.

Chloride and Carbonation Profiles

Concrete samples can be obtained to determine chloride ion penetration or carbonation, if that is suspected. Chloride samples may be obtained as powder through rotary hammer drilling, by cutting cores, or otherwise obtaining samples. If cores or other solid samples are used, the samples are ground prior to testing. Several test methods are available. AASHTO method T260, "Sampling and Testing for Chloride Ion

in Concrete and Concrete Raw Materials,” is often used. AASHTO method T260 procedure A provides for both acid-soluble and water-soluble chloride content analysis, either by potentiometric titration or ion-selective electrode. Procedure B of T260 employs the atomic adsorption method for determination of acid-soluble chloride content. ASTM International has two methods: C 1152 for acid-soluble chloride extraction, and C 1218 for water-soluble chloride extraction. For both methods, the extract is subsequently tested for chloride content using ASTM method C 114. Another method for testing for water-soluble chlorides that uses whole pieces of concrete rather than powdered samples is the American Concrete Institute (ACI) soxhlet extraction process, test method 222.1.

Acid-soluble chloride ion testing is also known as total chloride testing. If chloride ions are contained in the aggregate, acid-soluble testing will include those ions, even if they normally would not be a significant contributor to in situ corrosion. If chloride-bearing aggregate or chloride ions were otherwise present in the initial concrete mix, conducting water-soluble chloride and/or soxhlet tests can aid in data discrimination. For example, water-soluble testing of some central North American limestone coarse aggregates may show chloride ion contents up to 0.1%, yet no corrosion problems with these aggregates has been reported (Ref 129). The ACI 222.1 soxhlet method has shown the ability to remove chloride ions from the concrete while not extracting significant amounts of chloride from the coarse aggregate.

As shown in Fig. 19, chloride threshold values depend on the quality of the concrete and local moisture conditions. Because chloride ions may effectively be bound in aggregate or in the cement paste, the threshold also depends on the analytical method. For a thorough discussion of these issues refer to Ref 129.

Carbonation test samples are conducted on freshly fractured concrete specimens obtained by coring or other means. The depth of carbonation is determined by applying a fine mist of phenolphthalein solution employed as a pH indicator. An aqueous solution of 1% phenolphthalein dissolved in 70% ethyl alcohol will provide a good pH indicator (Ref 130). Non-carbonated areas will turn magenta on application of the phenolphthalein solution, whereas carbonated areas will not.

Corrosion Rate Testing and Other Advanced Techniques

Corrosion rate testing has been applied in the field to investigate corrosion of reinforced-concrete bridges and highways. Most work has involved the linear polarization technique, typically employing a guard ring to contain the applied current. The galvanostatic pulse technique has also been employed. Obtaining meaningful results with these testing approaches requires more than casual familiarity with the techniques. Acoustic testing, such as pulse echo, and ground-penetrating radar have been employed with some success to identify corrosion problems in reinforced concrete. Several variations in radiography have also been tried.

Inspection of Steel Elements

Characteristics to be noted depend on the component of the structure.

Painted steel inspection includes defining the condition of the coating. This can range from:

- Little evidence of corrosion, suggesting that the coating is sound
- Some chalking or peeling but no exposed metal
- Moderate to heavy surface rust

- Coating system has failed
- Corrosion has caused sufficient section loss to warrant a structural evaluation.

Weathering steel inspection would look to identify:

- Tightly adhering oxide layer with little or no section loss
- Some surface rust or pitting with a granular or dusty oxide layer
- Measurable section loss due to corrosion, some flaking
- Corrosion is advanced, with laminar sheets of rust present.

Steel pin or hanger inspection would include similar inspection breakdowns, as given previously for painted steel and weathering steel. Additional attention should be given to crevice areas, particularly if salt spray or drainage problems are an issue.

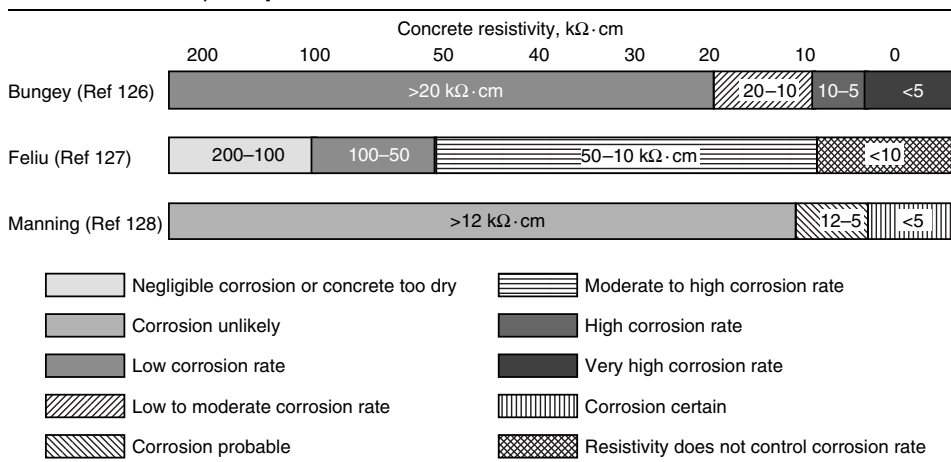

Steel culvert inspection would look to identify that:

- The culvert shows little deterioration, if galvanizing is present and if it is in good condition.
- There is slight to moderate corrosion, particularly on the invert; there is minor damage or separation of seams.
- There is significant corrosion and some through-pits on the invert; there is minor to moderate distortion, deflection, or separation of the seams.
- Major corrosion is present, with obvious distortion, deflection, or settlement.

Bearing inspection would look to identify that:

- The bearing shows minimal signs of corrosion.
- There is moderate to heavy corrosion, with perhaps some pitting, but the bearing is still functioning.
- Heavy corrosion has occurred with section loss; shear keys may have failed, or corrosion may restrict motion.

Table 4 Resistivity and possible corrosion rates

Corrosion-Resistant Reinforcement

Jack Tinnea, Tinnea & Associates, LLC

Corrosion-resistant reinforcement (CRR) is employed in bridges and highways in efforts to help reduce the staggering maintenance costs related to infrastructure corrosion. The CRR has taken many forms, often novel, to extend the service life of reinforced-concrete highway structures that range from simple reinforced-concrete culverts to bridges soaring over wide rivers.

Approaches to Corrosion Resistance

The CRR has taken three major paths to achieve its goal of reducing vulnerability to corrosion. These include:

- Coated metal reinforcement
- Use of corrosion-resistant alloys
- Replacement of metal reinforcement with nonmetallic products

A problem in the development of CRR stems from the fact that the extended life conditions, which reinforced-concrete structures experience in the as-constructed environment, are not easily replicated in accelerated testing protocols. Furthermore, new high-performance concretes (HPC) and a general move toward placing greater concrete cover over reinforcement greatly impede the influx of corrosive ions such as chlorides. This in turn means that the CRR will exist in a high-pH environment for decades before it becomes necessary for the CRR to provide improved corrosion resistance.

Selecting the appropriate design approach for corrosion control in a reinforced-concrete structure requires a clear estimate of the desired service life. That seems simple but often is problematic in the public works area. For example, if it is likely that a highway bridge will become functionally obsolete in 40 years due to expected traffic volume increases, it may not make economic sense to specify 100 year service life materials by selecting an HPC mix, which provides exceptional resistance to chloride ion penetration, and coupling that with 316LN stainless steel reinforcement. However, many reinforced-concrete bridges remain in use well beyond their planned service lives and continue as important parts of local infrastructures. Evaluation of the potential for functional obsolescence requires input from planners and traffic engineers. In short, making a proper estimate of a reinforced-concrete highway structure requires a multidisciplinary team. Working with a multidisciplinary team makes unique demands on management, but the savings that result, particularly in large projects, can yield handsome returns.

Economics and Life Cycle. Growth in China, India, and other countries has led to volatility in the costs of construction materials. In 2003, the price of plain reinforcing bar increased 55%; in 2004, the increase was only 1.2%, and in 2005, the price dropped 7.4% (Ref 131). Such economic pressures are not likely to abate in the foreseeable future, so inclusion of specific costs in this article could lead to serious error. However, given the general trends over the past decade, it is possible to understand when it is reasonable in highway and bridge design to proceed with one type of material over another.

Figure 24 compares relative costs for several types of reinforcing bar versus the age of the structure. The microcomposite alloy is a proprietary steel, MMFX-II, that meets ASTM A

1035 (Ref 132). It is an alloy that is almost free of interlath carbides, with a microstructure that consists of nanosheets of austenite between laths of dislocated martensite or ferrite (Ref 133). For this representation, it is assumed that the structure is located in an aggressive environment with chloride ion exposure. It is also assumed that the concrete cover will provide 25 years of protection before the chloride ion concentration reaches the threshold necessary for corrosion of carbon steel. The onset of corrosion for both epoxy-coated reinforcement (ECR) and carbon steel is shown to occur at the same time, because the base metals are the same. A 5 year propagation period is assumed for carbon steel, while a 10 year propagation period is assumed for ECR. The increase in total cost during those two propagation periods is from either rehabilitation or replacement. It is assumed that the chloride ion threshold for the microcomposite alloy is twice that of carbon steel. After corrosion commences, it is assumed that the microcomposite will behave in a manner similar to carbon steel and show a 5 year propagation period. The two cost lines for 304 and 316 stainless steel are not expected to increase during the 60+ years shown in Fig. 24.

It appears reasonable to assume that with improved concretes and increased cover, today's (2006) bridge in an aggressive environment can expect to provide 20 to 30 years' service or more before uncoated ASTM A615 (Ref 134) black steel reinforcement will start to show signs of corrosion. Work performed by the Virginia Department of Transportation found that with newer construction techniques, such as low-w/c concrete and adequate concrete cover, less than 25% of all Virginia bridge decks would require rehabilitation within 100 years (Ref 135). The studied Virginia bridges include those exposed to marine environments, high deicing salt applications, and traffic, and others, typically in rural areas, that see no marine exposure, less traffic, and hence less frequent deicer applications.

Options. There are other options beyond materials selection that can dramatically extend

the service life of a highway structure. Some are the simple steps of paying attention to detailing. Run-off water from a bridge deck often contains chloride-bearing deicing salts. This can be particularly problematic on curved or skewed bridge decks. If only scuppers are used that are fitted with short drain pipes, the wind may carry salt-water that drains to support piles and causes corrosion in an area where it could easily and very inexpensively be avoided. If a 100 year design life is desired and posttensioning (PT) is to be part of the design, it is reasonable to use the best technology available to avoid premature corrosion of the PT strands. It is also relatively inexpensive insurance to include spare empty PT strand ducts that, although sealed during construction, are readily available for installation of supplementary PT strands, should loss of prestressing occur. Figure 25 is a picture of a bridge where this technique was employed.

Epoxy-Coated Reinforcement

The ECR provides protection to carbon steel reinforcement by providing a barrier to potentially corrosive conditions, such as exposure to chloride ions. The coating is applied by fusion bonding, where a 100% dry powder mixture of epoxy resins, curing agents, pigments, fillers, and other additives is electrostatically applied to a preheated steel surface. The applied heat melts the powder constituents, which then react to form a cross-linked polymer coating. The first field installation of ECR was in 1973 on a bridge deck near Philadelphia, Pennsylvania.

Effectiveness of ECR. Since 1973, the presence of ECR has become commonplace on highway and bridge construction sites. Many early studies indicated that the technology appeared capable of providing effective corrosion control for reinforced-concrete structures in the highway and bridge arena (Ref 136–138). In 1992, an article was published by an early proponent of the technology that questioned ECR effectiveness (Ref 139). A year later, a news article (Ref 140) documented the debate. At the 85th meeting of the Transportation Research

Fig. 24 Relative life costs of corrosion-resistant reinforcement

Fig. 25 Alesia Bay Bridge, Waldport, Oregon. Courtesy of Oregon Department of Transportation

Board (TRB) in 2006, a panel discussion was held on the pros and cons of using ECR (Ref 141); it showed that the debate has not been resolved.

Between the start of the debate in 1992 and the TRB panel discussion in 2006, a number of reports, papers, and articles were prepared on ECR. Some of these discussed problems with ECR not providing significant corrosion control (Ref 142–144), while others reported good performance with the technique (Ref 145–147). Between these two extremes were researchers who reported mixed results on the level of corrosion protection provided by ECR (Ref 83, 148–150). To better understand the performance of ECR, a brief discussion of several issues from the literature follows.

Coating Disbondment. NACE International defines disbondment as “the loss of adhesion between a coating and the substrate.” It is not unusual for organic coatings to take up water when they are exposed to wet, damp, or humid environments (Ref 151). Water moves through the coating either at capillaries or pores (Ref 152) or by attacking relatively hydrophilic areas of low-molecular-weight/poorly cross-linked material (Ref 153). The water produces a multimolecular layer that moves laterally along the epoxy-steel interface. The formation of this water layer produces a loss in adhesion between the epoxy and the steel. For purposes of discussion, this is called wet adhesion loss.

A second form of coating disbondment can result from corrosion processes (Ref 149, 154). This can occur from either undercutting at the boundary of a corroding site or through cathodic disbondment, which occurs at a distance and often generates blisters rather than multimolecular layer separations.

Wet loss of adhesion can occur within four years of installation and is not necessarily associated with visible corrosion (Ref 143, 154). The wet adhesion loss can be substantially recovered if the reinforcing bars that have suffered that loss are dried (Ref 155). However, although adhesion recovery is possible for ECR dried in a laboratory, the concrete is likely to retain a high relative humidity at reinforcement depth in most highways and bridges, and such self-healing may not occur. Disbondment that results from corrosion undercutting or blisters formed during cathodic processes will never recover lost adhesion.

Coating Protection and Corrosion. Nicks, cuts, and other defects in the epoxy coating can result in the underlying carbon steel being directly exposed to the surrounding environment. For this reason, most specifications that include ECR discuss proper handling, placement, and coating repair prior to the placement of concrete. Even with the inclusion of special handling provisions, researchers in Texas reported that “experience has shown that epoxy-coated steel is treated like uncoated steel at the project site” (Ref 156). Figures 26 and 27 illustrate failures to observe proper handling at a major Midwestern construction site.

Coating with Defects. Figure 28 shows a schematic drawing of coating degradation that occurs as the result of a coating defect. The figure and discussion follow a model outlined by Nguyen and his colleagues at the National Institute of Standards and Technology (NIST) (Ref 153). In Fig. 28(a), step 1 is the formation of the coating defect, and step 2 is the transport of water and other reactants, such as oxygen and chloride ions, to the metal surface. Steps 3 and 4 are the formation of the anode (corrosion site) and cathode(s).

In Fig. 28(b), note that the cathodic reaction is not benign, because it leads to delamination of the coating. Here, the sodium ion is part of a hydrolysis reaction that produces an alkaline solution at the metal-coating interface:

Sodium ions diffuse along the metal-coating interface (step 5) and initiate blisters at a distance (step 6). In Fig. 28(c), this alkaline solution then creates an osmotic pressure gradient (step 7), the main force behind blister growth (step 8). Step 9 is the anodic hydrolysis reaction:

The reaction shown in Eq 11 produces hydrochloric acid that will reduce the local pH and

Fig. 26 Bare reinforcement cage resting on a loose pile of epoxy-coated reinforcement

Fig. 27 Epoxy-coated reinforcement (ECR) loosely stacked on in-place ECR

accelerate corrosion. It is to avoid this corrosion process that strict handling and placement specifications typically are employed for structures with ECR bars. Problems with coating defects can greatly increase subsequent corrosion.

Coating without Defects. However, even without field-detectable defects, epoxy coatings have pathways or pores that can be involved in absorption and diffusion of water and sodium and chloride ions. Figure 29 shows a schematic of the NIST model for coating degradation without pre-existing defects (Ref 153). In Fig. 29(a), the gray hydrophilic regions are areas with low-molecular-weight materials that have relatively little cross linking. As such, they can take up water and ions and are subject to hydrolysis.

The hydrolysis and dissolution of the hydrophilic regions are, in fact, an attack by water that eventually leads to the formation of pathways through the epoxy coating to the steel surface

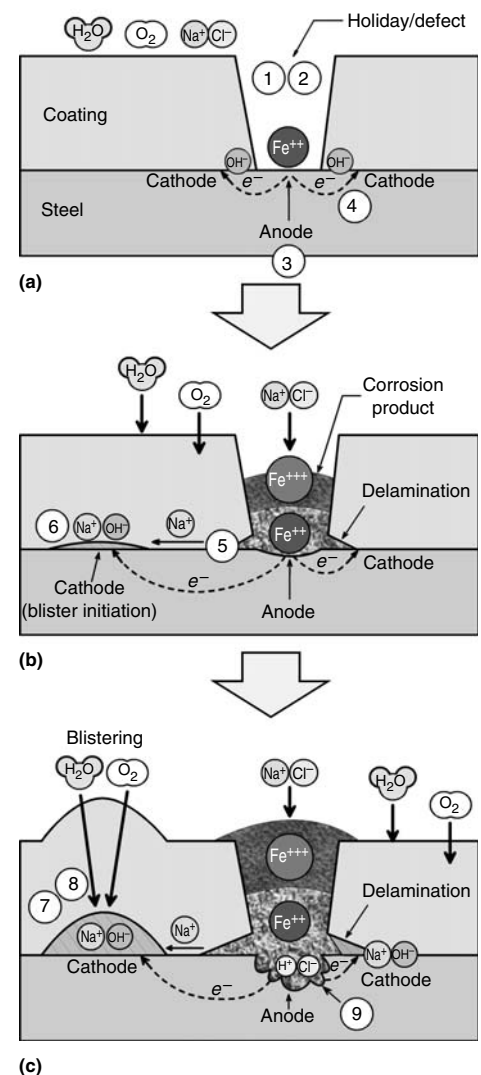

Fig. 28 Failure at a coating defect

(step 1 in Fig. 29b). As in the case of ECR with a defect, water and reactants reach the steel (step 2), leading to the formation of anodes and cathodes (steps 3 and 4, respectively).

In Fig. 29(c), the small and mobile sodium ion diffuses along the steel-coating interface in step 5. Through hydrolysis (step 6), alkaline solutions develop. This leads to delamination of the coating adjacent to the conductive pathway.

In Fig. 29(d) (step 7), the alkaline pools generate osmotic pressure gradients that transport water to the reaction site. This inflow of water and expansion due to the formation of corrosion products causes swelling and blister formation in step 8. Generally speaking, the corrosion observed on initially undamaged ECR is much less than that seen with damaged bar (Ref 150).

Fig. 29 Failure without a coating defect

Hydrolysis. For both initially undamaged and damaged coatings (Fig. 28c and 29d), step 9 shows pits forming in the steel as the result of hydrolysis reactions. These reactions are aggravated by the presence of chloride ions, because iron will form soluble complexes with chlorides. These complexes aid in the removal of reaction products from the active site. Hydrolysis also will reduce the local pH.

Control of the Cathodic Reaction. The ECR was initially employed to shield steel reinforcement from a corrosive environment. To many, this meant ECR protected steel from aggressive ions such as chlorides. Given this view, many structures were built with both ECR and uncoated steel. In particular, it is the practice of some agencies to use ECR for the top mat of a bridge deck and uncoated black steel on the bottom mat. The logic is that the top mat is protected from chloride-bearing deicers by the epoxy coating, while the bottom mat has such a deep concrete cover that corrosion is not likely to occur.

This thinking does not account for the fact that if ECR were used in the bottom mat, the epoxy coating would shield that steel from oxygen, which is necessary for the corrosion process. Corrosion of steel in concrete is typically in cathodic control, being limited by the diffusion rate of oxygen through the concrete. The presence of an epoxy coating greatly diminishes oxygen availability at the steel surface (Ref 157, 158). Even with special chairs and ties, it is unlikely that an ECR top mat will be completely electrically isolated from a bare steel bottom mat. When chloride ions reach threshold level at a defect in the ECR top mat, this will create a small anode connected to a very large uncoated carbon steel bottom mat cathode (Ref 159). These small anode/large cathode situations can lead to localized corrosion of reinforcement with significant section loss that does not generate tensile hoop stresses, cracking, or delamination.

Modified ECR Techniques. Additional protection has been attempted to provide integral protection for the almost unavoidable holidays and coating defects. These attempts include the use of inhibitors in the concrete and the coating. An arc-sprayed zinc coating was recently applied to reinforcing bar before applying the epoxy coating (Ref 64). Self-healing resins are also being investigated.

Manufacture and Construction. The coating application, fabrication, handling, and installation of ECR are covered under the standards and practices listed in Table 5.

Stainless Steels and Microcomposite Alloys

The rationale for using stainless steels and microcomposite alloys in highways and bridges is quite simple. These alloys are more resistant to chloride contamination than are carbon steels, and they have substantially higher chloride ion thresholds. A higher chloride ion threshold means that if other factors remain constant, it will take a longer time to reach the corrosion threshold, so a longer maintenance-free service life is enjoyed.

An early example of the use of stainless steel reinforcement is in a marine pier constructed between 1937 and 1941 in Progreso, Mexico. A recent inspection of that pier showed that even with chloride concentrations of approximately 1.2 wt% of dry concrete measured at reinforcement depth, the structure was showing no signs of general corrosion problems after 60 years service (Ref 63). The chemistry of the alloy used in the Progreso pier is similar to type 304.

Stainless steels are iron alloys that produce a corrosion-resistant chromium oxide layer on their surfaces. This generally requires a minimum of 11 to 12% Cr. Other materials, such as nickel, molybdenum, nitrogen, and others, are

added to improve mechanical properties, provide resistance to chloride-environment pitting, and improve strength. For example, by lowering carbon content, the L-grades improve corrosion resistance but reduce the yield strength. By adding nitrogen, the N-grades raise the strength of L-grades back toward that of standard grades and provide added corrosion protection. Stainless steel reinforcement is available at a cost premium compared to carbon steel alternatives.

Stainless Steel Alloys. Alloys used in bridges and highways include the austenitic alloys 304 (S30400), 316 (S31600), and XM19 (S20910) and the duplex alloys 2101 and 2205 (S31803). Ferritic stainless alloys, such as 3Cr12 (S41003) and CRS 100, are also being used as reinforcement. Specialty alloys are also employed, such as Nitronic 60 (S21800) for galling situations and XM29 (S24000) where nonmagnetic steels may be required.

Microcomposite Alloy. ASTM A 1035 describes a Fe-C-Cr-Mn alloy that has an average chromium content of ~9%. Although high, that chromium content does not reach the threshold of 10.5% used in defining stainless steels. The corrosion resistance derives from a morphology where the nanometer structure consists of dislocated martensite or ferrite phases separated by austenite sheets. In addition to corrosion resistance, this structure provides increased strength, qualifying as ASTM A615 grade 75.

Corrosion Resistance. Table 6 is a matrix showing several corrosion-resistance indexes for carbon steel, several stainless steels, and the microcomposite alloy.

The pitting resistance equivalent number (PREN) shown in Table 6 is a number that gives a general guideline in evaluating pitting resistance. For stainless steels in concrete, there is a general correlation between PREN and the chloride ion threshold (Ref 167). The chloride ion threshold "Carbon steel index" sets carbon steel as the base, with a value of 1, and expresses the other alloy chloride ion corrosion threshold

as a multiple of that observed for carbon steel. The data were obtained from outdoor southern exposure protocol (Ref 168) specimens that followed a weekly regimen of ponding with a saturated NaCl solution for three days and drying for four days (Ref 64). The chloride ion threshold " Cl^-/OH^- ratio" expresses the chloride ion corrosion threshold as the molar ratio of the chloride and hydroxyl ions.

In an effort to reduce costs, stainless-steel-clad conventional reinforcements have been produced. Although stainless steel has a relatively high hydrogen overvoltage and as such does not make as good a cathode as, for example, passive carbon steel in concrete, problems have been observed when defects are present either at the ends, bends, or at the seams of stainless-clad reinforcement (Ref 64, 166, 169). Welding clad reinforcement in the field could also be problematic. The data in Table 6 also suggest potential problems with cladding defects or where seams have separated during fabrication.

To place these corrosion-resistant reinforcement (CRR) alloys in an exact order according to corrosion resistance when used as reinforcement in concrete is difficult through accelerated laboratory testing. Generally, as stated previously, there is reasonable correlation between the PREN number and corrosion resistance. Again, accelerated testing can be helpful, but long-term behavior may differ. For example, in the over 60 year old Progresso pier, the chloride ion concentration of 1.2 wt% at the level of the stainless steel bar exceeded literature-reported lab study thresholds for stainless steels of between 0.7 and 1.0 (Ref 63).

Applications. An extensive study of corrosion-resistant reinforcements stated that stainless steel reinforcing bar should provide a service life in excess of 100 years, even with concrete cracking (Ref 170). This study also recommended the use of 316 alloys over 304 alloys for conventional reinforcement in marine structures and bridges where repair closure is particularly problematic. Stainless

alloys can also be beneficial for doweling applications.

In addition to reinforcement, stainless steels may be used for hinged arches (Ref 171). Figure 30 shows an arch hinge used on a coastal bridge. As can be seen, the tide sometimes covers parts of the hinge. The hinge plates were fabricated from duplex stainless steel 2205, while antigalling Nitronic 60 was used for the pins. Figure 31 shows the 316LN studs used to connect the hinges to the concrete arch and abutment.

Costs. Although more expensive than plain carbon steel or ECR, life-cycle cost analysis clearly shows stainless steel is preferable for bridges in high-traffic areas subject to deicing salts or in marine environments (Ref 142, 171). Cost comparisons between ECR and stainless need to look at installation costs in addition to materials costs. For example, as was discussed earlier, ECR requires special handling to avoid incidental damage during construction. Figure 32 shows that with stainless steel reinforcement, workers can walk on placed mats without damaging the system or inducing future corrosion (Ref 171). This can substantially reduce construction costs. With CRR, it is also good practice to specify use of stainless steel chairs, tie wires, and incidental hardware that workers find easier to use than similar specialty hardware employed to place ECR. On three new

Fig. 31 316LN anchor studs used to connect stainless steel arch hinge to concrete

coast bridges in Oregon, the cost premium for using stainless steel reinforcement compared to black iron bars was only 10% of the total project cost (Ref 172).

As mentioned previously, some CRR metals, such as A1035, have higher strength than carbon steel. Because A1035 also qualifies as ASTM A615 grade 75, designers can reduce the amount of steel required with a similar design using ASTM A615 grade 60 reinforcement. Reducing the amount of steel required helps reduce the typical CRR materials cost premium. Further, reductions in the amount of steel required in congested areas will also reduce labor costs.

Galvanized Reinforcement

Galvanized reinforcement is another option to control corrosion in reinforced-concrete highway and bridge structures. Typically, the coating is applied by the hot dip process, where the reinforcement is immersed in a molten zinc bath. The coatings that form include several iron-zinc intermetallic layers covered with essentially pure zinc as the outer layer. This zinc coating provides both a barrier coating on the carbon steel and sacrificial cathodic protection (Ref 173). Zinc is protected by a passive surface film at pH values between approximately 6 and 12.5 (Ref 174).

Fresh concrete is quite alkaline, with the pH typically well above the 12.5 pH passive upper limit. When zinc is first exposed to this environment, the reaction is vigorous, producing calcium hydroxyzincate precipitate and generating hydrogen gas. This process stops after the final set of the concrete. If local sources of portland cement are particularly alkaline, it is suggested that some trial mixes be made that employ mineral admixtures such as fly ash or silica fume. These additions can help moderate excessively high pH during early hydration and, if properly used, will also provide a concrete that is less permeable to chloride ion penetration. Secondary mineralization, where the zinc replaces calcium in the cement-phase matrix, continues at a much reduced rate, forming and

maintaining a good barrier coating to the reinforcement.

Passivation of carbon steel reinforcement will be lost if the pore water pH drops below approximately 11.5. Also, the ratio of chloride ions to hydroxyl ions impacts corrosion, so if chloride ions are present, passivation may be lost at higher pH values. Zinc-coated steel has been shown to remain passive to approximately pH 9.5. Further, galvanized bars have been shown to resist corrosion at much higher chloride levels, at least 2.5 times higher, than bare carbon steel (Ref 175).

In-depth inspection of two bridge decks fabricated with galvanized reinforcement showed little evidence of corrosion after almost 30 years in service (Ref 173). In fact, metallographic examination of rebar samples obtained from the two bridges indicated that the remaining zinc coating thickness exceeded ASTM A 767 class II requirements for new bars.

Performance of Weathering Steel Bridges in North America

Frank Pianca,
Ontario Ministry of Transportation

The first major step in obtaining public acceptance of weathering steel in North America occurred in 1963 when Eero Saarinen, a well-known architect, selected this steel to construct a building in Moline, Illinois. The first use of weathering steel in a highway bridge occurred in 1964. The market for weathering steel began to expand rapidly in the 1960s as the unique combination of corrosion resistance and strength properties caught the eye of the design engineer, along with the potential advantages of low maintenance, freedom from painting, and weight savings.

In contrast to the introduction of most new materials and products, which follow a lengthy procedure of laboratory testing and field trials, there was a total commitment from many transportation agencies to the use of weathering steel.

Steel industry records indicate that the use of weathering steel in bridges increased each year to a high in 1980, when it accounted for approximately 12% of the total steel awarded for bridges. In that same year, the state of Michigan instituted a complete moratorium on the use of uncoated weathering steel in its highway program, because of reported problems with some of its weathering steel bridges.

Thereafter, the use of weathering steel in bridges declined to a low of approximately 10% in 1987, but, as painting costs continued to rise and a better understanding of the nature of the corrosion problems developed, the use of this

steel again began to climb. By the end of 1989, the use of weathering steel had risen to a new high level of approximately 15%. In 1990, the Michigan Department of Transportation (DOT) rescinded the moratorium and agreed once again to consider the use of weathering steel for new bridges.

Weathering Steel as a Material

Weathering steel is a low-alloy steel containing up to 3% of alloying elements such as copper, chromium, nickel, vanadium, phosphorus, silicon, and manganese. Of all the elements listed, copper, nickel, chromium, and silicon contribute most to improving the atmospheric corrosion resistance. Weathering steel is also known as atmospheric corrosion-resistant steel and is marketed under the trade names of several steel companies. In Canada, the applicable material specification is CSA G40.21 type A, and in the United States, ASTM A588 (the grade most commonly used on bridges).

On exposure to the atmosphere and under suitable conditions, the corrosion rates of weathering steels are considerably less than ordinary mild steel in the same environment. As the steel weathers, it forms an oxide that is light colored, loose, and fine grained. Further oxidation results in a tightly adhering stable oxide film, or patina, that is rough, dark brown in color, and inhibits further corrosion. The rapidity with which weathering steel develops a stable patina and its characteristic color is determined largely by the atmospheric conditions of exposure. The time required has been quoted as generally more than 18 months (but less than 3 years) to many years.

It is instructive to examine the conditions most favorable for the development of a stable patina. They are exposure to intermittent wetting and drying, such as is provided by direct exposure to rain, wind, and sun, and the absence of corrosive pollutants, particularly salt. Experience has shown that the presence of salt prevents the formation of a stable oxide, and corrosion proceeds unchecked. The design, fabrication, erection, and maintenance of weathering steel structures play a major role in assuring satisfactory performance.

Rate of Corrosion of Weathering Steel

A number of studies have been carried out to measure the rate of corrosion of weathering steel. Many of the studies have included a comparison with other steels. A direct comparison with mild steel is difficult, because the inclusion of scrap metal in the production of mild steel can result in composition variation that results in differing corrosion performance. A typical figure is that weathering steel has an atmospheric corrosion resistance of approximately 1.5 to 4 times that of carbon steel containing no alloyed

Fig. 32 Workers can walk on stainless steel bar, where they should not with epoxy-coated reinforcement.

copper. However, it is the actual corrosion rates that are of interest, rather than whether or not weathering steel performs well or badly in relation to a material, carbon or mild steels, that would not be used unprotected in outdoor environments.

The corrosion penetration rate found for weathering steel in a variety of bridges that are performing satisfactorily ranges from 3 to 7.5 $\mu\text{m}/\text{year}/\text{surface}$ (0.12 to 0.30 mil/year/surface). Weathering steel corroding at a rate higher than 7.5 $\mu\text{m}/\text{year}/\text{surface}$ (0.30 mil/year/surface) cannot be expected to develop a protective oxide coating.

Performance of Weathering Steel

A study undertaken by the Michigan DOT in the late 1970s showed bridge corrosion problems associated with the contamination of weathering steel surfaces by deicing salts. Some design details that permitted crevice corrosion, galvanic corrosion, or the accumulation of deicers resulted in serious corrosion damage. These findings led to a decision to impose a partial moratorium on the use of weathering steel in Michigan bridges. The moratorium, instituted May 2, 1979, prohibited the use of unpainted steel in depressed roadway sections (where the most serious corrosion problems were observed) and in urban and industrial areas where heavy salting and industrial pollution created a corrosive environment. On February 6, 1980, the moratorium was made statewide.

In response to the Michigan moratorium, a study was launched under the auspices of the American Iron and Steel Institute (AISI) that included the examination of 49 weathering steel bridges in seven states. An analysis of the 49 bridges indicated the following:

- Thirty percent of the bridges showed good performance in all areas.
- Fifty-eight percent of the bridges showed good overall performance, with moderate corrosion in some areas.
- Twelve percent of the bridges showed good overall performance, with heavy localized corrosion in some areas.

The areas that exhibited moderate-to-heavy corrosion were found to be those most frequently subjected to contact with salt-laden road runoff passing through leaking and open expansion joints. Tunnellike conditions, particularly where the underclearance was less than 6 m (20 ft), also were detrimental, because they resulted in splashing and deposition of salt-laden snow onto the bottom of the beams.

The inspection results did indicate the need for remedial painting of certain portions of bridges exhibiting excessive corrosive attack. The report also stated that there was a need for additional research on the development of suitable painting systems for weathering steel subject to corrosive attack.

At approximately the same time, the National Cooperative Highway Research Program (NCHRP) initiated a study to build on the AISI findings. The major findings of the NCHRP investigation were "... that weathering steel can provide a satisfactory service life with limited maintenance if the structural details are designed in a manner that prevents accelerated attack, vulnerable areas are painted, and contamination with chlorides is avoided."

Michigan rescinded the moratorium in 1990, and the Michigan DOT decided to consider the use of weathering steel whenever a proposed bridge location was within the guidelines of the Federal Highway Administration Technical Advisory, October 1989.

Figure 33 shows a protective patina tightly adhering to weathering steel on the exterior of a cable-stay-supported bridge. The relative humidity at the bridge location averages over 80% for four months and over 70% for the remainder of the year. Figure 34 shows a light-colored sheet of weathering steel corrosion product peeling from the interior of the cable stay support pier adjacent to the exterior view shown in Fig. 33. This wallpaper-like corrosion product has a thickness of approximately 2.5 mm (0.1 in.). Although near the coast, corrosion product samples from the interior show no signs that chloride ions aggravated the corrosion. The clear difference in behavior between interior and exterior exposure appears to be the result of the high time of wetness that occurs within the piers. Thus, the interior environment minimizes the alternating wet-dry cycle necessary to produce a protective patina, and instead of protection, the interior conditions produce exfoliation of sheets of corrosion product.

Recommendations and Considerations on the Use of Weathering Steel

The most important considerations in designing a weathering steel bridge are preventing water ponding, diverting the flow

of runoff water away from the steel superstructure, preventing the accumulation of debris that traps moisture, and avoiding environments in which the bridge would be contaminated with salt.

Leaking joints are the most serious and common cause of corrosion problems in weathering steel bridges. Runoff water leaking through the deck joints persistently wets the bearings, flanges, webs, stiffeners, and diaphragms in the vicinity of the joint, where it can migrate for long distances along the bottom flange and wick up the web.

To avoid the problems created by leaking expansion joints, bridges should have a continuous superstructure, fixed or integral bearings at piers or abutments, and no bridge deck expansion joints unless absolutely necessary. When expansion joints cannot be avoided, they should be provided only at abutments.

It has been suggested that weathering steel coupons be used for up to two years to determine if corrosion rates are acceptable. It is desirable to monitor the atmosphere for constituents such as chlorides, sulfur dioxide, and moisture. Although no specific data define acceptable times of wetness for weathering steel, times greater than 60% are usually considered very damp for corrosion purposes. This can include low-level water crossings that may lead to high humidity and frequently wet conditions. Over stagnant or sheltered water, vertical clearance to the bottom flange of the bridge girder on bridges should be at least 3 m (9.8 ft), and over moving water at least 2.5 m (8.2 ft).

For aesthetic reasons, every effort should be made to minimize unsightly rust staining of concrete supports visible to the public by preventing runoff water from draining over the weathering steel and onto the concrete.

The color and texture of mill scale do not match those of corroded weathering steel surfaces. Unless mill scale is removed, the steel surface will appear matted, flaky, and not uniform for several years, depending on the degree of exposure and the aggressiveness of the local

Fig. 33 Protective patina tightly adhering to weathering steel on bridge exterior

Fig. 34 Wallpaper-like corrosion product peeling from weathering steel on bridge interior

environment. Therefore, all surfaces visible to the public should be blast cleaned. Near-white blast cleaning is recommended for weathering steel surfaces exposed to public view, and commercial blast cleaning for surfaces not visible to the public.

Combinations of high traffic speed, low clearance, and heavy use of deicing salt on the lower roadway pose a severe corrosion hazard. The spray plume kicked up by passing trucks is approximately twice as high as the truck and settles on the vulnerable overhead low points of the structure.

Inspection and Maintenance. An effective inspection and maintenance program is essential to ensuring that a weathering steel bridge reaches its design life. Weathering steel is not a maintenance-free material. The following examples illustrate the type of periodic maintenance that may be needed:

- Removing loose debris with a jet of compressed air or vacuum-cleaning equipment
- Scraping off sheets of delaminated rust
- High-pressure hosing of wet debris and aggressive agents from the steel surfaces
- Tracing leaks to their sources
- Repairing leaky joints
- Installing drainage systems, drip plates, and deflector plates that divert runoff water away from the superstructure and abutments
- Cleaning drains and downspouts
- Cleaning and caulking all crevices
- Remedially painting areas of excessive corrosion

Rehabilitation. Weathering steel bridges that are undergoing a high degree of uniform or local corrosion must be remedially painted to protect the affected areas against further section loss. However, little information is available on the long-term performance of coating systems over weathered A588 steel substrates. In the absence of such information, coating systems are often recommended based on their performance over uncoated weathering steel or carbon steel. This area has been identified in a number of studies as requiring further research work.

Conclusion

All available data indicate that good performance of uncoated weathering steel bridges is attainable. With the proper application of guidelines, bridge owners and consultants can be assured of obtaining consistently good performance with their weathering steel bridges. However, weathering steel does not provide a service life for the superstructure that is entirely free from maintenance. Proper detailing and choice of a suitable environment can reduce the need for some, but not all, maintenance. An effective inspection and maintenance program is essential to ensuring that a weathering steel bridge reaches its design life.

Coatings

Bryant "Web" Chandler,
Greenman Pedersen, Inc.

According to the U.S. Federal Highway Administration, there are just under 600,000 bridges (6 m, or 20 ft, and longer) in the national highway system, of which 190,000 to 210,000 are steel structures. They all require protection from corrosion in one way or another.

Barrier Coatings for Steel

The best way to protect steel bridges is by the use of coatings. Coatings provide protection as a barrier coat and/or for cathodic protection (CP). As a barrier, the coating isolates the metallic substrate from the electrolyte, thus eliminating one of the essential ingredients for corrosion.

Electrolytes such as liquids that include deicing salts and chemicals, salt air, acid rain, industrial pollutants, and engine exhaust gases, will promote corrosion. A good barrier coat will provide the needed isolation of the electrolyte. However, all coatings are permeable to moisture, and thus, the electrolytes or soluble salts (chlorides, sulfates, and nitrates) must be removed from the steel before coating application. If the soluble salts are not removed, then moisture is drawn through the coating, creating a condition called osmotic blistering. These blisters will break, exposing the bare steel and resulting in corrosion. There are several different testing procedures available to determine the presence of soluble salts.

Barrier coats, prior to the banning of coatings in the 1990s that contained a high volume of volatile organic compounds, included vinyl, chlorinated rubber, alkyds, low-solids epoxy, epoxy phenolics, urethanes, and other miscellaneous coatings. They have been replaced with acrylics, high-solids zinc-rich primers, high-solids epoxy, epoxy mastic, urethanes, moisture-cured urethanes, and siloxanes. Low-viscosity 100% solids (no solvent) penetrating primers are available where proper surface preparation is not possible. Advanced-technology epoxies, moisture-cured urethanes, and siloxanes can be applied and will cure below 0 °C (32 °F). This feature extends the traditional painting season.

The coatings that protect the metallic bridges by CP include zinc-rich primers and thermal spray materials. The most common thermal spray coating (TSC) used on bridges in the United States is an alloy of zinc and aluminum (85%Zn-15%Al) applied by the electric arc or flame spray process. The thermal spray process melts the wire or powder and sprays the molten droplets onto the substrate with the aid of compressed air. The TSC bond to the steel structure is

not metallurgical but mechanical; thus, a very clean abrasive-blast profile is required to obtain a good adhesion strength, something greater than 5 MPa (700 psi). The process of TSC application leaves a slightly porous coating and should be sealed within 8 to 12 h after application, before oxides have a chance to form. The viscosity of the sealer should be relatively thin so as to penetrate the pores of the TSC and only add 13 to 38 µm (0.5 to 1.5 mils) of coating thickness. A color coat can be added for aesthetic reasons and will yield longer corrosion protection to the TSC, much the same as painting galvanized steel does.

The zinc-rich primers that protect by CP include inorganic and organic binders. The binder holds the zinc particles in place and provides the intimate contact with the steel. The binder for inorganic zinc is typically a silicate. Binders for organic zinc coatings include epoxies and urethanes. The application of inorganic zinc requires an experienced applicator and a cleaner blast surface than organic zincs. Inorganic zinc is most often applied in a shop environment. Field touchup of inorganic zinc is normally done with organic zinc.

Bridges erected or painted prior to the mid-1970s were commonly painted with a red lead primer, an excellent low-cost corrosion-inhibiting pigment but containing a hazardous heavy metal and often including cadmium and chromium in the topcoats. These coatings were tolerant of minimal surface preparation. Those old bridges are now requiring complete repainting, considerable maintenance painting, or overcoating. Maintenance painting and/or overcoating requires close evaluation of the old coating to determine if it is justifiable and can support additional paint that will increase the stresses already present in the old coating. An evaluation would include the extent of failed paint or corrosion, the adhesion, the paint thickness, and the budget. Environmental or human factors may enter the evaluation process as well if the location of the bridge is close to schools, playgrounds, or other sensitive receptors to hazardous heavy metals.

Bridge design plays a big part in corrosion prevention. Complex truss bridge design is more prone to corrosion than the girder design. The decks of girder bridges are supported underneath by transverse floor beams and longitudinal steel girders, all relying on piers to support the structure—a fairly simple structure with few corrosion-prone areas. Conversely, truss bridges, both through-truss and under-the-deck truss, have many locations that are prone to entrapment of dirt, debris, and moisture, precursors to corrosion. The entrapment areas are often locations of high structural stresses, all the more important to prevent corrosion with the use of coatings.

Weathering steel does not normally require a protective coating. However, deicing salts can have a very adverse effect. As a result, weathering steel that is subject to frequent wetting from the bridge deck runoff should be protected

with multiple barrier coats. Those areas to be protected include the steel immediately under bridge deck expansion joints, abutments, deck drains, and so on.

Concrete Sealers

Despite its durability, concrete is a porous material, which means it can absorb water, chlorides, stains, and other water- or oil-based materials that it comes in contact with. It is necessary to inhibit the transfer of chlorides or other soluble salts into the concrete, where they can attack bare carbon steel reinforcing steel (rebar) embedded within the concrete structure. Rebar, subject to corrosion, will cause spalling and cracking of the concrete due to the seven to ten times volume expansion with the formation of rust.

Sealers are the most widely used materials to restrict or prevent the penetration of soluble salts or other contaminants while allowing the surface to breathe, so moisture within the concrete does not become trapped.

Generally, there are two broad categories of sealers:

- Film formers block the penetration of water and contaminants by forming a barrier on the concrete surface. They may also impart a gloss or sheen, depending on their chemical makeup.
- Penetrants actually penetrate into the concrete surface to increase water repellency and resist stains on absorbent concrete. Usually, they provide invisible protection without changing the surface appearance.

The penetrant type of sealer is the most widely used on concrete bridges, especially on their decks to inhibit the intrusion of chlorides and other deicing chemicals. Boiled linseed oil thinned with mineral spirits had been the sealer of choice for many highway departments for many years, because it is relatively cheap and abundant but not without its faults. Linseed oil will run off or leach out from the concrete and pollute the environment.

Other types of sealers, both penetrants and film forming, include silanes, siloxanes and

siliconates, epoxies, gum resins and mineral gums, stearates, acrylics, silicates and fluoro-silicates, urethanes, polyesters, chlorinated rubber, silicones, and vinyls.

Important considerations and properties for sealers include penetration depth, ultraviolet resistance, reactivity of concrete materials, service life, chloride and water absorption, water vapor transmission, crack bridging, and deicer scaling resistance. These properties delay or prevent the onset of rebar corrosion and deicer scaling.

Testing by various state transportation departments indicates that penetrating sealers work most effectively if they are applied within three to six months after bridge construction or concrete overlay, with repeated applications approximately every five years.

One of the popular generic penetrating sealers uses silicates that react with lime, alkali, and available moisture to seal the capillaries within the concrete. The sealant properties that control the reduction of concrete permeability are molecular size, viscosity, contact angle (wetting ability), and surface tension. Penetrating sealers do not have the ability to seal cracks and thus must be used in conjunction with a high-molecular-weight material to make an effective deck sealant that will prevent or slow down the migration of chloride ions to the rebar mat.

Electrochemical Techniques: Cathodic Protection, Chloride Extraction, and Realkalization

Jack Tinnea, Tinnea & Associates, LLC

Reinforcement in concrete does not normally corrode. This is because the concrete provides a high-pH environment, typically in excess of

12.4. The corrosion rate of mild and low-alloy steels typically employed as reinforcement in concrete is very low at high pH, because the metals form stable oxide layers and exhibit behavior similar to that of stainless steels. This behavior is known as passivation.

If the normal high pH of the concrete is lost, then corrosion can occur. Carbon dioxide in the atmosphere is able to do this through a process known as carbonation. Certain ions, such as chloride, are aggressive toward steel. If the concentration of an aggressive ion at the surface of the steel reaches a threshold level, corrosion will commence. The exact threshold level concentration is a function of the ion concentrations, pH, and oxygen availability.

A typical corroding area on a reinforcing bar is shown in Fig. 35(a). Corrosion occurs at the anode. The metal does not corrode at cathodic areas. A cross section of Fig. 35(a) is shown in Fig. 35(b). Note that corrosion is typically observed in the 10 to 2 o'clock position relative to the surface, with the rebar areas at greater depth continuing to manifest passive behavior. An electrical circuit analog of this corroding area is shown in Fig. 35(c).

The corrosion potential of steel embedded in concrete reflects both the anodic and cathodic reactions and is therefore a mixed potential. The rebar corrosion potentials are usually obtained with reference electrodes placed on the concrete surface. The corrosion potential readings often vary from location to location on the reinforced-concrete surface, sometimes 200 mV or more within 300 mm (1 ft).

Cathodic protection provides an electrical current to the reinforcement that polarizes the steel surface. Ideally, the application of CP makes all areas cathodic and thereby reduces the corrosion rate that would normally occur. With a successful CP system, the corrosion rate is reduced to levels that are acceptable or even to levels that have no engineering significance.

Electrochemical chloride extraction (ECE) can be looked upon as a high-current CP system that is applied on a temporary basis. The ECE process has been shown able to extract a significant quantity of chloride ions from contaminated reinforced concrete. The basic ECE processes can be modified to allow for realkalization of carbonated concrete.

Cathodic Protection

History of Cathodic Protection. Cathodic protection has been used for over 100 years to provide corrosion protection to metals exposed to waters and soils. The initial application of CP to steel embedded in concrete dates to laboratory work performed by Richard Stratfull and the California Department of Transportation in 1959 (Ref 176). It was not until the mid-to-late 1970s that full-scale demonstration projects were implemented (Ref 177, 178), and not until the late 1980s that application of such systems became routine.

It has been over 30 years since the first full-scale installation of a CP system to control corrosion of a reinforced-concrete structure. Since that time, acceptance of the process remains sporadic. Some large property owners, such as transportation ministries and departments, accept CP as an integral component of their restoration and maintenance strategy. However, they are industry exceptions. Even endorsement by the Administrator of the United States Department of Transportation's Federal Highway Administration resulted in acceptance of the technology by only a few of the 50 different state departments of transportation.

Why were owners reluctant to embrace CP? There are several reasons for this hesitation. Lack of familiarity with the technology is clearly one factor. Corroding and deteriorating concrete structures tend to be the province of civil engineers. Most early approaches to controlling reinforcement corrosion were simply to remove the unsound concrete and patch the structure. This approach involved technology familiar to the owners and engineers. In time, it became apparent that a "chip-and-patch" solution leads to chipping and patching greater areas each year.

Retaining specialty engineers to design CP systems did not appear to be the principal impediment to acceptance of the technology. Hesitation over embracing CP included concerns over life-cycle costs of a cathodic system versus the life-cycle costs of installing a new bridge deck. Another issue is costs for long-term maintenance of the systems by specialty contractors. There is often significant variation in the relative restoration costs, depending on the agency involved and the design style employed for the bridges and bridge decks.

Elements of a CP System. There are four elements to a CP system. These are the anode, cathode, electrolyte, and metallic path, shown in Fig. 36(a). In a concrete CP system, the cathode is the reinforcement or other embedded metals. The anode is either embedded in the concrete or affixed to the structure surface. The metal path is the reinforcement, reinforcement tie wires, and electrical cables installed as part of the CP system installation. The electrolyte is the concrete.

The electric current in the anode, cathode, and metallic path is carried by electrons, while in the electrolyte the current is carried by ions. Although concrete is not thought of as a con-

ductor of electricity, if it were unable to conduct electricity, there would not be a corrosion problem. As stated earlier, concrete consists of coarse and fine aggregate bonded by hydrated cement. Within this matrix, the conduction of electricity typically occurs in the cement phase.

The anode(s) can be embedded in the concrete, surface-applied, or remote to the reinforced concrete. Embedded anodes include anodes covered with concrete overlays or covered with shotcrete; anodes embedded in grouted jacket systems; anodes installed in slots sawn or holes drilled in the concrete; anodes installed in repair excavations; and anodes embedded in the original concrete at the time of construction. The last example, where CP anodes are installed during initial construction, is also known as cathodic prevention (Ref 179).

Anodes can be applied to the surface of the concrete as coatings or with conductive adhesives. Coatings include carbon-loaded organic coatings and thermal-spray-applied metal coatings. If the reinforced-concrete is partially submerged or buried, it is possible to use submerged or buried anodes that are located remote from the reinforced-concrete structure. Figure 36(b) shows a remote CP configuration. Note that a second electrolyte (i.e., soil or water) is shown in series between the anodic reactions and the bulk concrete resistivity. For applications in seawater, the level of the tide must be included in design considerations. Remote submerged anodes are only able to provide protective current to areas that are submerged. In remote submerged anode systems, the resistivity of the bulk concrete rapidly attenuates the protective current flowing to embedded reinforcement located above the waterline.

Note that in Fig. 36(a) and (b), protective current should flow to all of the reinforcement. The goal of CP is to polarize all portions of the reinforcement to a cathodic potential that suppresses corrosion even in crevices or at the base of pits. That is achieved by polarizing the structure to a potential equivalent to, or more negative than, the corrosion potential of the most anodic site. The geometry and variations in electrolyte resistivity of the structure can result in uneven CP current densities collecting on the reinforcement surface at different locations in

the area being protected, with some areas receiving too much current while others receive currents that are insufficient to provide complete protection. Situations of adverse current-density disparity can be avoided with proper attention during the CP system design.

Types of CP Systems. Cathodic protection systems derive the necessary electric potential from an impressed-current source or from the galvanic action of sacrificial anodes.

Impressed-Current Systems. The driving voltage necessary to power CP systems can come from external direct current (dc) power supplies. To provide external power, a transformer is coupled with a rectifier to convert available alternating current (ac) to dc of an appropriate voltage range, as shown in Fig. 37(a). This approach is known as impressed-current cathodic protection (ICCP). Anodes employed in ICCP systems include inert metals such as titanium with metal oxide coatings, carbon-loaded coatings and fillers, conductive ceramics, and soluble metallic anodes such as zinc. The rectifier is placed in the metallic path, shown in Fig. 37(a), with its positive terminal connected to the anode and its negative terminal to the reinforcement, the cathode.

With an ICCP system, the output voltage can be adjusted. With this feature, if the concrete resistivity increases, for example, from drying during the summer, the output voltage can be increased to overcome the increased circuit resistance. Conversely, if seasonal wetting reduces the concrete resistivity, the rectifier can be adjusted to decrease the current output. Some commercially available rectifiers have the capacity to automatically adjust the output to respond to preset voltage, current, or reinforcement potential parameters.

Galvanic Anode Systems. Galvanic anodes used in sacrificial cathodic protection (SACP) provide a potential that does not require dc or rectified ac power. The SACP employs a metal that is more electrochemically active than the one to be protected. Active metals such as aluminum, magnesium, zinc, and their alloys are typically used as galvanic anodes for mild steel. In SACP, a direct electrical connection is made between the galvanic anode and the metal to be protected, as shown in Fig. 37(b). This is a

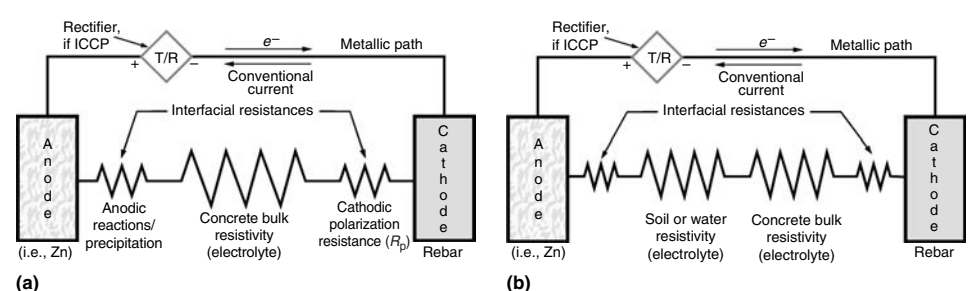

Fig. 36 Electrical circuit analog of reinforced-concrete cathodic protection system components. (a) Anode is embedded or affixed to structure. (b) Anodes installed remote from the reinforced-concrete structure. ICCP, impressed-current cathodic protection; T/R, transformer/rectifier

sacrificial process whereby the galvanic anode corrodes, thus generating the electric current that cathodically protects the other metal.

The SACP provides a simple system that will not lead to conditions of overprotection. However, the output of SACP systems cannot be easily adjusted. The inability to readily adjust the galvanic output presents the designer with limitations on where SACP may be applied. It may be possible to extend the range of SACP systems by augmenting the initial output through the temporary use of rectifiers or zinc-air batteries.

How CP Controls Corrosion. Figure 38 is an Evans diagram of SACP applied in a neutral or alkaline environment. Because cement is alkaline, this diagram is appropriate to discuss using CP to control the corrosion of steel in concrete. The ordinate in Fig. 38 reflects the steel (reinforcement) potential measured with respect to a reference electrode, and the abscissa is the log of the corrosion current. The rate of corrosion is directly proportional to the corrosion current.

Three anodic curves and one cathodic curve are shown. The curves are labeled with the dominant reaction. The anodic curves are the three straight lines that angle up to the right at approximately 30° . The cathodic curve starts angling down to the right, then plunges in an almost vertical direction and finally returns to angling down to the right. The line labeled with the reaction $\text{Fe} \rightarrow \text{Fe}^{2+} + 2e^-$ is the reaction for the corrosion of iron. Note that this curve crosses the heavier cathodic reaction curve at the point labeled "Corr." This location (potential) represents a condition where steel reinforcement is freely corroding in an alkaline concrete environment. On the ordinate, this point is identified as $E_{\text{corr}, S}$ (the corrosion potential for the reinforcement), and as I_A on the abscissa (the corrosion current).

Parallel to and below the iron anodic curve is a curve for zinc corrosion in a similar environ-

ment. Zinc is more electronegative than steel. If the zinc is connected to the steel, the steel will be polarized in a negative direction (potential) to the point labeled "CP." This is the mixed potential for the steel-zinc electrochemical couple. Note the marked reduction in the iron corrosion rate that is attained by polarizing to this potential. The Evans diagram in Fig. 38 provides a brief introduction to the traditional basis for CP. In concrete, however, the opportunity exists to alter the environment surrounding the reinforcement. This is a situation that is not typically possible in applications of CP in natural waters or even soils.

CP Design Overview. Most of the early applications of CP to reinforced-concrete structures were ICCP systems, and ICCP requires routine monitoring by specialty contractors. The SACP is an inherently simpler technology than ICCP and requires far less monitoring. Although there were several installations of SACP systems early in the development of CP for reinforced structures, there was little reporting of their success. Part of that absence from the literature derived from early papers reporting that high current densities, ranging from 10 to over 30 mA/m^2 , were required for effective CP (Ref 180, 181).

General Design Considerations. Design of CP systems is beyond the scope of this article. See the article "Cathodic Protection" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. Several texts discuss CP of concrete reinforcement (Ref 38, 182, 183). NACE International has published several relevant documents (Ref 184–189).

Other standards that address CP of reinforced concrete include the European Union's EN 12696:2000, "Cathodic Protection of Steel in Concrete, Part 1: Atmospherically Exposed Concrete" (Ref 190), Australian standard AS 2832.5, "Cathodic Protection of Metals—Steel in Concrete Structure" (Ref 191), and the Norwegian NORSOK standard M-503 (Ref 192).

NORSOK-503 only briefly addresses CP of concrete.

Specific Design Considerations. Generally, CP is applied to bare black steel reinforced-concrete structures. It can also be applied to prestressing steels, but special care is required to avoid excessive polarization, hydrogen evolution, and embrittlement of the high-strength steels employed (Ref 186). Cathodic protection of epoxy-coated reinforcement can be problematic because of electrical continuity problems introduced by the presence of the epoxy coating and the likelihood of significant portions of the reinforcement network being electrically isolated from each other. Beyond the basic corrosion issues that affect the application of CP, there are other factors that impact the restoration decision process. These include:

- Availability of alternate vehicle traffic routes during restoration or replacement
- Availability of ac electrical power
- Historic value of the structure
- Use of stay-in-place formwork
- Use of epoxy-coated reinforcement
- Use of resin injection, waterproofing, or other electrically nonconductive materials
- Size of the structure
- Presence of prestressing elements
- Shoreline considerations

Current Requirement. A portion of the basis for early practice to employ relatively high current densities came from attempts to polarize the reinforcement potential to levels used to protect pipes in soil and marine environments. Because these current densities typically were beyond the

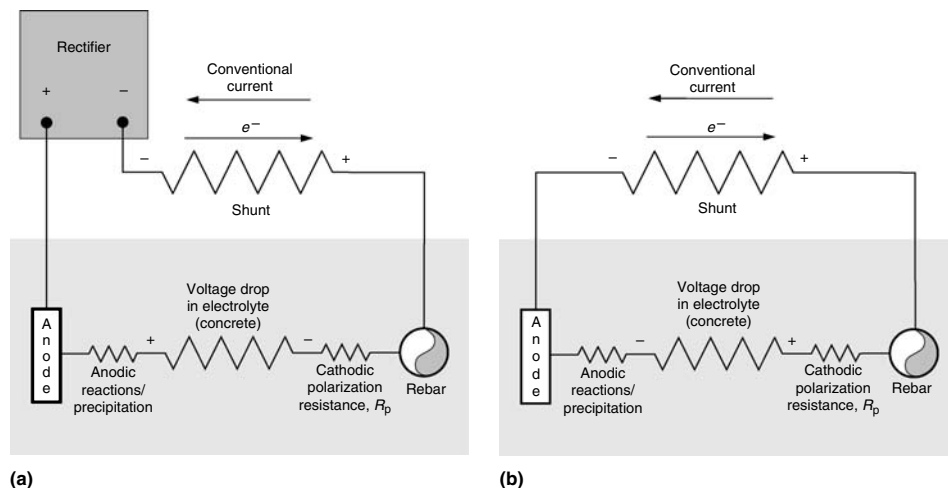

Fig. 37 System components for cathodic protection. (a) Impressed current. (b) Sacrificial or galvanic system

Fig. 38 Evans diagram for the application of a galvanic cathodic protection (CP) system. Note: Log current is the absolute value of the current density, where both the anodic and cathodic currents are plotted as positive values. See the text for description.

capacity of most galvanic systems, development of SACP was impeded.

In time, it was noted that substantially less current was required for effective CP (Ref 193). A system that employed perforated zinc sheets on a bridge deck with a porous asphalt overlay, which was initially believed to provide insufficient current output, proved successful in effective long-term corrosion control (Ref 194). Success with SACP was also reported with similar perforated zinc sheets in protecting marine piling (Ref 195). The perforated zinc sheets for both installations came from scrap metal left over from the manufacture of U.S. pennies.

Effective protection of bare steel in quiet seawater requires CP currents of approximately 20 to 30 mA/m² of uncoated steel (Ref 196). Cathodic protection currents in the range of 0.5 to 1 mA/m² are required to provide similar protection to bare steel buried in many natural soils with resistivities of 5 to 15 Ω·m, while resistivities of 15 to 400 Ω·m for a similar level of protection will require currents of only 0.1 to 0.5 mA/m² (Ref 196).

Currents on the order of 1 to 7 mA/m² may be required to fully polarize actively corroding areas when CP is first applied to corroding steel in concrete (Ref 197). Subsequent to polarization, CP may typically be maintained with significantly smaller currents that range from 0.25 to 1.0 mA/m² (Ref 198–200). Protection of piling in subtropical marine splash zones may require higher currents—5 mA/m² to protect epoxy-coated reinforcement, and 10 mA/m² to protect bare reinforcement (Ref 201).

It is not surprising that less current is required to protect steel reinforcement in concrete than steel in seawater. Several factors are responsible. It is reasonable to expect seawater to have a much higher concentration of aggressive ions, such as chloride or sulfate, than high-resistivity natural soils. In addition, oxygen availability is expected to be less for steel buried in soil than steel exposed to seawater. Both of these factors lead to expectations that less CP current will be required to protect a structure buried in the soil than the current needed to protect that same structure if it were submerged in seawater.

Resistance in Circuit. Electrical resistance plays a major role in the effectiveness of CP of reinforced-concrete structures. The output of a CP system follows Ohm's law, $E = IR$, where E is output voltage, I is CP current, and R is the total circuit resistance. Resistance impedes the current output of the CP system and, depending on where that resistance occurs, can influence its effectiveness. An increase in resistance at the reinforcement surface reflects reduced corrosion and is desirable. Variation in resistance in other areas produces variation in the CP system output. Typical approaches to CP design attempt to address these factors. The relatively fixed output voltage of SACP systems means that they are more impacted by system resistance than are ICCP systems.

The overall CP system circuit resistance as applied to concrete structures comes from several sources, including:

- Concrete resistivity
- Concrete-anode interfacial resistance
- Concrete-reinforcement interfacial resistance
- Resistance between individual elements of the reinforcement network

Concrete resistivity depends on several factors. These include the initial concrete mix design, the presence of mobile soluble salts in the pore water, and the moisture content of the cement. Addition of mineral admixtures, such as silica fume or fly ash, can increase a concrete resistivity. The presence of chloride ions can reduce a concrete resistivity. However, the largest single contributor to the resistivity of a concrete is the concrete moisture content. The resistivity of any concrete is much lower when its moisture content is high than when it is dry.

Cathodic protection systems are broken down into zones to assist in output control. If adjacent areas vary in initial bulk concrete resistivity, a higher current will flow to the area with lower concrete resistivity. Designing zone breaks to separate those areas of different concrete resistivity can provide better current control and direct how much current is applied to the different areas.

Interfacial resistance at the anode, however, does not improve corrosion protection. In fact, efforts are undertaken to reduce anode-concrete interfacial resistance (ACIR) and thereby increase current output of both ICCP and SACP systems. Several processes involved may act to produce increases in ACIR. One is simply moisture content. This is particularly true with atmospherically exposed CP systems where the anode is applied at or near the concrete surface and where normal variations in local rainfall and humidity produce variations in the level of concrete pore saturation. The ACIR will drop on cool, wet, and humid days and increase on hot and dry days (Ref 172).

Another source of ACIR increase derives from anode material precipitating in the cement pores, reducing their effective hydraulic radius. This process is known as secondary mineralization and has been observed on CP systems that employ metallized zinc-bearing coatings (Ref 202). Zinc is able to replace calcium in the cement matrix and can produce almost a water-proofing effect.

Humectants, which are hygroscopic and attract water, have been employed to counteract drying in the cement pores surrounding CP anodes. Included in these attempts are lithium salts and calcium chloride (Ref 203, 204). Lithium salts also help to avoid alkali-silica reactions that can be an issue with some aggregates employed in concrete.

Polarization resistance, R_p , is the resistance at the concrete-reinforcement interface. Changes in R_p reflect the likelihood of corrosion. Initially, in uncontaminated concrete where the pH is high (~13), the reinforcement R_p value is relatively high, because the steel is passive and the corrosion rate is low (Fig. 39a). The R_p is reflected in the slope of the line identified with the reaction label $\text{Fe} \rightarrow \text{Fe}^{2+} + 2e^-$, and the anodic Tafel constant, β_a , is shown as >700 mV per decade. Note that the corrosion potentials are relatively electropositive and tightly clustered, and the slope of the iron oxidation line is steep.

Contamination by chloride ions or loss of pH through carbonation can initiate corrosion. With the onset of corrosion, the observed R_p becomes less. In Fig. 39(b), a second iron oxidation line is added, showing active corrosion and an anodic Tafel constant $\beta_a < 150$ mV per decade. The slope flattens for active corrosion iron oxidation reaction, and reinforcement potentials become more electronegative and dispersed. On corroding reinforced structures, a family of $\text{Fe} \rightarrow \text{Fe}^{2+} + 2e^-$ curves would fill between the two lines shown in Fig. 39(b). The different iron oxidation reaction slopes would reflect the local conditions, such as the ratio of chloride ions to hydroxyl ions ($[\text{Cl}^-]/[\text{OH}^-]$), pH, and oxygen availability.

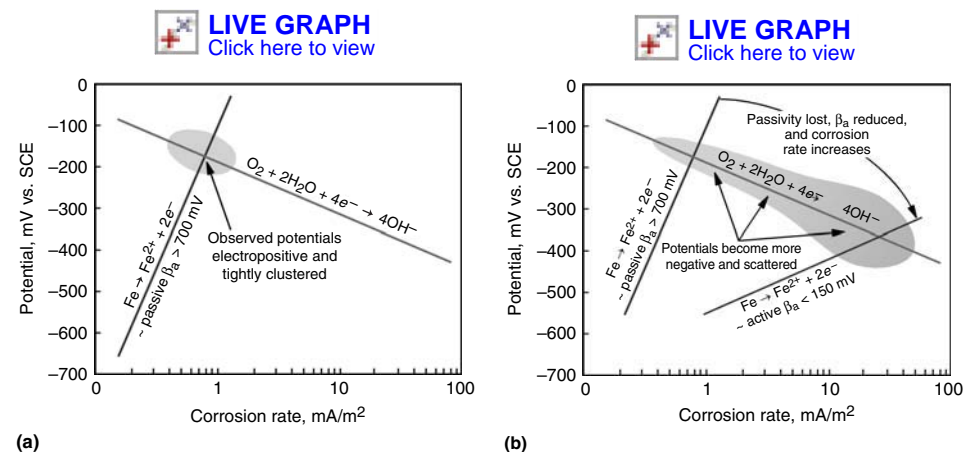

Fig. 39 Current-potential diagrams. (a) Passive conditions. Tafel slope, $\beta_a > 700$ mV. (b) Corroding conditions. Tafel slope, $\beta_a < 150$ mV. Corrosion occurs as passivity is lost and active corrosion proceeds. SCE, saturated calomel electrode

The application of CP changes the reaction at the reinforcement surface from iron oxidation, $\text{Fe} \rightarrow \text{Fe}^{2+} + 2e^-$, to oxygen reduction $\frac{1}{2}\text{O}_2 + \text{H}_2\text{O} + 2e^- \rightarrow 2\text{OH}^-$. The passage of CP current will move chloride ions away from the reinforcement, and soluble alkali ions, such as sodium and potassium, toward the rebar. With time, CP affects chloride removal and increases the pH (realkalization). These processes return the environment surrounding the reinforcement to one that supports passive behavior of the embedded steel. If a properly operated CP system is turned off and allowed to depolarize, the observed steel oxidation R_p increases (Fig. 40; also Ref 199). Note that in Fig. 40, the reinforcement corrosion potentials become more electropositive and more tightly clustered. If CP was not able to change the environment surrounding the embedded reinforcement, it would be much less effective. In the lower right of Fig. 40, the application of 40 mA/m² of CP current is shown. Following the actively corroding iron oxidation line, $\beta_a < 150$ mV, the application of CP reduces the pre-CP corrosion current of 25 mA/m² to 18 mA/m², a corrosion rate too high to sustain structure durability. However, through the removal of chloride ions, realkalization, and a return to a passive iron oxidation line, $\beta_a > 700$ mV, the resulting repassivation produces a far greater corrosion rate reduction.

Figure 41 shows a Pourbaix diagram of the repassivation process. When a reinforced-concrete structure is first constructed, the embedded steel is in the passive regime, as indicated by point "P." In this example, carbonation of the concrete reduces the pH, initiating active corrosion (as show by the arrow from "P" to point "A"). The initial application of CP polarizes the steel to point "CP_i." With time, realkalization increases the pH, moving the steel to point "CP_f." If the CP systems were turned off, the steel would then return to point "P."

Fig. 40 Cathodic protection (CP) of reinforcement can lead to repassivation of the rebar when chloride ions migrate from rebar and/or realkalization of the concrete surrounding the rebar occurs. Under these conditions, the CP can be removed. The rebar will depolarize and return to passive conditions, as shown. When chloride ions return to the rebar surface or pH is again lost, corrosion reoccurs.

Figure 42(a) shows the polarization decay of a CP system zone that had been in operation for over five years (Ref 194). The CP anode system was a saw-slot type installed on a bridge deck. This installation configuration allowed measuring reinforcing-steel corrosion potentials on a square grid of 1.5 m (5 ft). The ordinate of Fig. 42(a) is the average of 200 individual corrosion potential readings relative to a copper-copper sulfate electrode (CSE). The abscissa is the time that the 200 readings were obtained. Note that depolarization continues throughout the 90 day testing period. Also note that after approximately 30 days, the average corrosion potential reflects a return to passive conditions. The depolarization testing was terminated after 90 days.

Table 7 lists statistics for the pre-CP and 90 day depolarized (post-CP) corrosion potentials shown in Fig. 42(a). The post-CP mean corrosion potential for the depolarized rebar is almost 100 mV less active (more electropositive) than the pre-CP value. The most active post-CP reading, -219 mV, is over 300 mV more positive (less active) than the most active pre-CP reading. Pre-CP readings reflect multimodal behavior, with some areas actively corroding and others not. The post-CP data more closely follow standard distribution, as reflected by its lower standard deviation, skewness, and kurtosis. Standard deviation is a metric of the spread or dispersion of a data set. Skewness describes the degree of asymmetry of the sample distribution.

Fig. 41 Path of cathodically protected steel through an Fe-H₂O Pourbaix diagram. Using cathodic protection (CP), the corrosion rate is substantially reduced. Under favorable conditions, chloride ions migrate from the rebar surface, alkalinity is reestablished in the concrete surrounding the rebar, and the reinforcement then will reflect passive behavior when the CP current is removed. SHE, standard hydrogen electrode

Positive skewness indicates that the distribution tails toward more positive values, while negative skewness indicates that the distribution tails in a

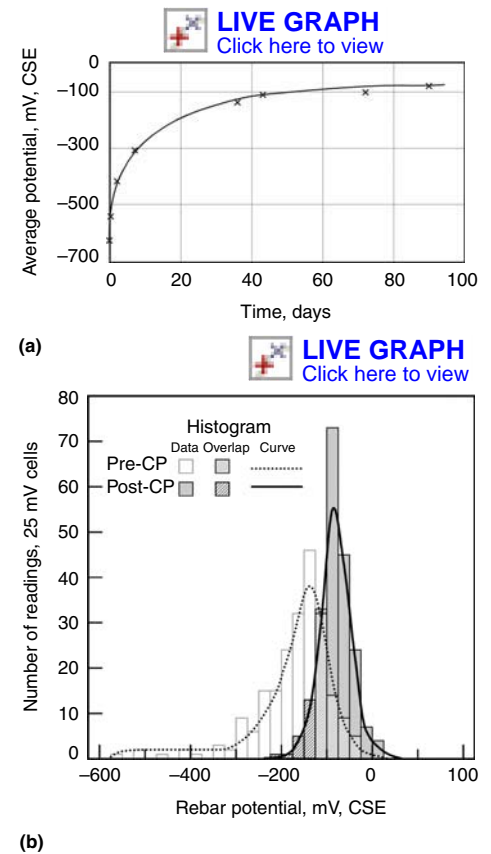

Fig. 42 (a) Decay of average corrosion potential over a 90 day period. Each data point is the average of 200 individual readings obtained on a square grid of 1.5 m (5 ft) on center over an entire cathodic protection (CP) zone (saw-slot-style anode system). No additional readings were obtained after 90 days. If the CP system were left turned off indefinitely, chloride ions would diffuse back to the steel surface, and corrosion would again commence. (b) Histograms for pre- and post-CP potential surveys of the same CP zone. Post-CP survey potentials were obtained after 90 day depolarization. The abscissa shows the rebar potential observed. Each histogram cell (the rectangular columns) is 25 mV wide. The height of the histogram cell, corresponding to the ordinate value, reflects the number of readings observed within each 25 mV cell. Curves for the two data sets smooth the histogram stair steps. For both data sets, individual readings were obtained on a square grid of 1.5 m (5 ft) on center over an entire CP zone (saw-slot-style anode system). CSE, copper-copper sulfate electrode

Table 7 Pre- and post-cathodic protection (CP) rebar potential data

Variable	Pre-CP	90 day depolarization
Sample size	220	206
Mean, mV, CSE	-170	-82

negative direction. The kurtosis of a data set characterizes vertical asymmetry from normal distribution. Positive kurtosis reflects peaked distribution, while negative kurtosis indicates flattened distribution. The data in Table 7 reflect that this application of CP current was able to return the reinforcement to a passive environment, with the observed corrosion potentials more positive and tightly clustered, following the pattern shown in Fig. 40.

Figure 42(b) shows histograms of the pre-CP and 90 day depolarization post-CP data sets. The abscissa in Fig. 42(b) reflects the measured reinforcement corrosion potential (mV, CSE). For both sets, the histogram cell width was 25 mV. The ordinate for Fig. 42(b) is the reading observed in each 25 mV wide cell. Smoothed curves overlay their respective histogram. The pre-CP readings show a much broader data set that tails to the left (more negative/more corroding corrosion potentials). The tail of the pre-CP readings is reflected in the -1.76 skewness of the pre-CP data set compared to almost no skew with the post-CP data. Both data sets are more peaked than a normal distribution curve, with the post-CP kurtosis much less than that of the pre-CP. The histograms in Fig. 42(b) and the statistics in Table 7 show that post-CP readings are much more tightly clustered and better follow a normal distribution curve than do the pre-CP readings. The pre-CP readings include areas of active corrosion, while the 90 day depolarized post-CP readings reflect a return of passive conditions. This observed statistical behavior of the corroding pre-CP data follows previous observations and discussions that abrupt changes in rebar potential are indicative of corrosion activity. The use of statistics is then a valuable tool to use with absolute corrosion potential values in interpreting bridge data.

Resistance in the reinforcement network can lead to some elements being effectively isolated from the CP system. Generally, when reinforced-concrete structures are fabricated, electrical continuity between the reinforcement bars is not specifically addressed. The standard practice of overlapped bars, multiple crossings between longitudinal and transverse bars, and the use of metal tie wires to secure reinforcement prior to placing concrete provides reasonably good electrical continuity. However, prior to the design of a CP system, it is important to have a sense of the degree of electrical continuity within the reinforcement network.

Effect of Environmental Factors on CP. For SACP systems, environmental factors may require greater attention than is necessary for ICCP systems. If the concrete dries or there is a substantial increase in the ACIR, one may simply increase the output voltage of an ICCP system to sustain the desired output of CP current. With SACP systems, it is not possible to make such simple adjustments.

Temperature impact on SACP current output has its foundation in the Arrhenius equation. The output from sacrificial systems depends on the corrosion rate of the galvanic anode material. As

with most chemical reactions, the rate of corrosion can be expressed as follows:

$$\text{rate} = k[A]^a[B]^b \quad (\text{Eq 12})$$

where the rate is in $\text{mol dm}^{-3}\text{s}^{-1}$, k is the rate constant, a and b are the order of reaction with respect to the reactants A and B, respectively, and $[A]$ and $[B]$ are concentrations in mol dm^{-3} .

The rate constant is determined from the Arrhenius equation:

$$k = Ae^{-\frac{E_A}{RT}} \quad (\text{Eq 13})$$

where k is the rate constant, A is the frequency factor (derives from frequency of collisions and their orientation and is roughly constant over small temperature changes), e is the base for natural logarithms, E_A is the activation energy, R is the gas constant, and T is the absolute temperature in K.

If the impact of Arrhenius on the rate of reaction is examined, one can note a general guideline that an increase of 10°C doubles the reaction rate. For example, assume a reaction at 20°C is increased to 30°C and that the activation energy is 50 kJ mol^{-1} :

$$\text{At } 20^\circ\text{C: } e^{-\frac{E_A}{RT}} = e^{-\frac{50,000}{8.31 \times 293}} = 1.21 \times 10^{-9} \quad (\text{Eq 14})$$

$$\text{At } 30^\circ\text{C: } e^{-\frac{E_A}{RT}} = e^{-\frac{50,000}{8.31 \times 303}} = 2.38 \times 10^{-9} \quad (\text{Eq 15})$$

From this example, it can be seen that for reactions at approximately 20°C , which have activation energies of approximately 50 kJ mol^{-1} , the rate of reaction will approximately double for each 10°C increase in temperature.

For SACP systems applied as thermal-sprayed coatings, it is reasonable to assume that temperature will also affect metal loss at the surface. The literature reports significant variation in observed service lives for metallized CP systems. In Florida, the estimated service lives of metallized SACP in subtropical marine environments range from 5 to 10 years (Ref 205). Service lives of over 25 years based on bond strength are observed for metallized-zinc CP systems installed in temperate marine environments along the Oregon coast (Ref 206). In both examples, the majority of the bridges are not exposed to serious air pollution. The rainfall along the Oregon coast is higher than the Florida Keys, where many of the CP-protected structures are located. Also, the average relative humidity is slightly higher along the Oregon coast than in the Keys. Higher rainfall and humidity should make for a more aggressive environment and hence shorter service life for CP systems along the Oregon coast. One corrosion rate factor where Florida clearly exceeds Oregon is average annual temperature. The annual average temperature in Key West, Florida, is approximately 26°C (79°F), while in Newport, Oregon, it is only 10°C (50°F). If those temperatures are inserted into Eq 13, with E_A of 50 kJ mol^{-1} , the

rate constants are 1.78×10^{-9} and 5.69×10^{-10} for Key West and Newport, respectively. The "rule-of-thumb" approach in this example would lead one to predict that the corrosion rate of metallized-zinc coatings on Florida bridges may be expected to be approximately three times greater ($1.78 \times 10^{-9} \div 5.69 \times 10^{-10} = 3.1$) than that of Oregon coast bridges. That ratio approximates the observed service lives seen with field applications in the two areas.

Moisture is another environmental factor that can influence CP systems protecting concrete structures. The moisture content greatly influences the bulk resistivity of concrete and hence the output of any CP system. Rain, sunshine, and humidity can have large effects on reinforcement CP systems. The atmospheric exposure is typically much more dynamic than traditional buried and submerged environments for CP systems. Marine applications that are submerged do not see such variations, but areas in the tidal and splash zones can see significant moisture effects.

An example is a reinforced-concrete pile that supports a coastal bridge (Fig. 43). The lowest portions of the pile are buried in the mud or sand. Above that is a section of pile that is continually submerged. Above the submerged area is the tidal zone. The next area is what is known as the splash zone, and the last is the atmospheric zone. Adjacent to the zone identifications are typical relative rates of corrosion observed.

In areas just above high tide, the drying action of air and/or sun exposure can create a wicking action, where salt water that has entered the concrete evaporates. When the water evaporates, the sea salts remain behind. Repeated cycling of tides and evaporation can significantly concentrate chloride ions in this area.

Because many reinforced-concrete structures are directly exposed to the weather, any corrosion control efforts, including CP, should

Fig. 43 Marine tidal zones

examine drainage. Ponding of rainwater or splashed seawater on the concrete can accelerate corrosion. Local ponding, by increasing the local moisture content, can lead to localized areas where CP systems have unusually high current output. If attention to drainage and ponding is not included in the design, excessive currents can develop, leading to localized failure of the CP anodes (Ref 194, 202).

CP Criteria. Concrete, absent contamination by aggressive ions or the loss of pH through carbonation, provides a much different environment to embedded reinforcement than natural soils or waters do to buried or submerged steel. Typically, natural soils or waters do not provide an environment that passivates steel, as does concrete. Passivating conditions will be restored to the steel reinforcement if the application of CP can cause migration of chloride or other contaminating ions from the steel surface and/or return the high pH to the steel surface. In fact, it has been noted for some years that the operation of CP systems will dramatically reduce the chloride content in previously contaminated structures, as seen in Fig. 44 (Ref 194) and elsewhere (Ref 207, 208).

If structures that previously enjoyed long-term CP were allowed to depolarize over extended periods, it was noted that reinforcement in those previously protected structures exhibited characteristics similar to noncorroding, non-contaminated structures. If sufficient current can be applied to provide initial corrosion control, then with time, the chloride concentration at the level of the reinforcement should diminish (Fig. 44), and reduced current will be required to sustain protection (Fig. 39a, 40).

A minimum decay of reinforcement polarization of 100 mV is a generally accepted criterion for CP of steel in concrete (Ref 184, 209). This criterion is applicable for systems when the cathodic reaction is under mass-transfer control, while the anodic reaction is under activation control, and also when the cathodic reaction kinetics are under activation control (Ref 209). The former case reflects high corrosion rates or

those where the concrete pore structure is near saturation and the rate of oxygen diffusion controls the rate of corrosion. The latter case is typical of low current densities, and the basis for protection derives from the return of a high-pH/low-chloride environment around the reinforcement that restores passivation. Further discussion of CP criteria as applied to reinforced concrete appears in several NACE International publications (Ref 184–186).

CP Anode Configurations. In general terms, CP systems involve either distributed anodes or discrete anodes. Distributed anodes conform, more or less, to the surface of the concrete being covered. Discrete anodes are isolated individual installations and are typically located to address a specific corrosion area. It is possible to install discrete anodes as networked groups so they become more distributed in application. Before addressing current practice for reinforced concrete, the following brief discussion of earlier approaches, some of which are, at the time of this writing, still providing complete protection to the reinforcement, is included.

Conductive asphalt overlays applied to bridge decks were the original applications of CP to steel in concrete (Ref 176–178, 210). Conductivity was gained by adding carbon coke to the asphalt. Connection to the asphalt was typically made through the use of high-silicon cast iron “pancake” anodes. In a nomenclature that continues to this day, the cast iron anodes were called primary anodes, while the conductive overlay was called a secondary anode. These systems were effective from a corrosion standpoint. However, if the bridge did not have a previous overlay, the anodes added a significant dead load. Another problem with the coke addition is that it softened the asphalt and often would require a second course of nonmodified asphalt as a riding surface.

Cast-in-place conductive polymer secondary anodes have been installed in several forms. Some of the earliest involved a Federal Highway Administration (FHWA)-developed cast-in-place polymer. This polymer is a polyester type that was loaded with conductive carbon filler. Electrical connection and continuity of the polymer was achieved with graphite-fiber and/or platinized niobium-copper-cored primary anodes. Early attempts involved installation of the cast-in-place conductive anode material into slots cut into the riding surface of bridge decks. Although this approach avoided the dead-load issues of the conductive asphalt overlays, there were problems with wear of the polymer and having the polymer pop out of the slots.

To address anode wear and pop-out problems, a mound installation was developed. Here, the cast-in-place polymer secondary anode was installed as a mound on top of a scarified deck surface. Again, carbon-fiber or platinized primary anodes were employed to make connections and provide longitudinal continuity. After the conductive polymer cured, the deck was overlaid with a wearing course. The addition of

the wearing course again involves significant addition to dead weight.

Precast and extruded polymer secondary anodes were also used to apply CP to reinforced-concrete structures. The precast polymer anodes were most often fabricated using carbon-filled polyester resins. As with the cast-in-place installations, carbon-fiber or platinized primary anodes were run down the core of the precast anode to provide electrical connection and continuity should the resin crack. Some of these precast installations are still in operation.

The extruded polymer anodes were manufactured with copper core wires with a cross-linked carbon-filled outer polymer coating. These anodes tended not to weather well in bridge installations. The outer polymer tended to become brittle and crack. The copper core wire then failed at the cracks, and electrical continuity was lost (Ref 194).

Current practice ICCP systems include distributed and discrete anodes.

Distributed anode configurations include carbon-filled organic coatings, thermal-sprayed metal coatings, and rare earth catalyzed-titanium expanded mesh as secondary anodes. Primary anode materials and installations vary considerably. The two coating approaches are typically installed directly on the surface of reinforced sub- and superstructure elements. Zinc and catalyzed titanium are the most frequently used metals in the thermal spray installations. The catalyzed-titanium expanded mesh can be installed on decks that are overlain with a sufficiently conductive concrete or on sub- and/or superstructure elements by covering with a sufficiently conductive shotcrete.

Discrete anode configurations generally involve the use of catalyzed-titanium inserts or conductive ceramics. The conductive ceramics are a titanium suboxide material, usually in a tube form. These anodes are installed in holes drilled or cut into the concrete.

Current practice SACP systems likewise include distributed and discrete anodes.

Distributed anode configurations include thermal-sprayed metal coatings, expanded mesh, and perforated scrap material. Successful thermal spray metals include low-iron high-purity zinc (e.g., ASTM B418, type II), an 85-15 zinc-aluminum alloy, and a proprietary 88Al-12Zn-0.02 In alloy. High-purity zinc expanded mesh and scrap (Ref 195) has also been used successfully, particularly in wrapped or jacketed installations on concrete piles in marine environments (Ref 123). The SACP systems that use zinc sheets attached to the concrete surface with a proprietary hydrogel adhesive are still in operation but, at the time of this writing, are no longer being manufactured.

Discrete anodes are fabricated from small ingots of galvanic anode material. The SACP anodes provide protection by corroding. Because discrete anodes are typically embedded into the concrete, the volume of corrosion product generated by SACP anodes must be considered. For example, aluminum produces

Fig. 44 Chloride migration resulting from cathodic protection (CP)

high-volume corrosion products, and early attempts to use aluminum anodes generated cracks and delaminations of the concrete. Zinc corrosion products are not so voluminous and can actually replace calcium in the cement phase through a secondary mineralization process (Ref 202, 211). Because zinc is an amphoteric material, it is necessary to keep the pH in the bedding material high. Likewise, keeping the grout surrounding the discrete SACP anodes relatively moist will improve output by lowering the grout resistivity. To accomplish these ends, proprietary additives, such as lithium hydroxide and lithium halides, are employed in the fabrication and/or installation of discrete anodes.

CP Installation. Installation of CP systems involves several common issues, regardless of whether SACP or ICCP is employed. The following are brief discussions of these shared factors.

Repairs. It is important to make repairs that are compatible with CP. If nonconductive materials are used, such as injected epoxy, care should be exercised in their application. This is to avoid having the nonconductive material inadvertently shield reinforcement from the CP current source. Secondly, it is necessary to confirm electrical continuity of the reinforcement. Repairs typically afford the opportunity to perform this work, because reinforcement is usually exposed during this process.

Short Circuits. With ICCP, and sometimes with SACP, it is important to avoid creating short circuits between the impressed-current anode and the embedded reinforcement. With ICCP, short circuits can seriously cripple the system and adversely affect current distribution and the effectiveness of the system. With SACP systems, short circuits can limit the ability to monitor or control the system. Metal at or near the surface, such as tie wires and support chairs used to position reinforcement prior to concrete placement, can be a problem on soffits.

In many SACP systems, short circuits are not necessarily a problem. Some SACP systems are designed so that the impact of short circuits limiting system control is accepted and special short-free areas are created for monitoring. If reinforcement is exposed, direct connection

between the bar and the anode is possible. For example, Fig. 45 shows a thermal-sprayed zinc coating protecting both exposed and embedded reinforcement on a marine pile. Here, no primary anode was used. Rather, the zinc was directly sprayed on both the exposed reinforcement and over the surface of the adjacent sound concrete, protecting both exposed and buried steel.

Surface Preparation. When employing surface-applied coatings for either ICCP or SACP, care should be exercised during surface preparation. As with all coating projects, success in applying CP coatings starts with good surface preparation. Abrasive blasting is frequently employed, but care must be exercised to avoid excessive removal of the high-cement-content surface layer and exposing too much coarse aggregate. In concrete, it is the cement phase that is responsible for conducting electricity.

Figure 46(a) shows a proper abrasive blast that cleans the surface and provides a good profile to improve coating adhesion. Figure 46(b) shows a surface where too much cement-rich material has been removed. Note that a significant portion of the metallized coating is applied directly to coarse aggregate. Typically, coarse aggregate has a very much higher resistivity than the cement phase of concrete and also forms a weaker bond with the coating. The effective electrical contact area between the metallized coating and the underlying concrete is much less in Fig. 46(b) than in the situation shown in Fig. 46(a), because the gravel is such a poor electrical conductor. A CP system installed with a proper surface preparation, as shown in Fig. 46(a), will have far better current output than a system installed with a surface prepared as shown in Fig. 46(b).

CP System Energizing. After the system has been installed, it must be energized. Energizing and the initial evaluation of CP systems for

reinforced-concrete structures require the input of and testing by specialists. The most commonly employed criterion of CP is a potential decay of 100 mV. In unsaturated atmospherically-exposed concrete, where oxygen is readily available but the concrete is not too dry, polarization decay can occur within 4 h (Ref 184). For concrete with a high moisture content, which impedes oxygen transport, or very dry concrete, depolarization can take a longer time, 10 to 24 h or more. Australian standard AS 2832.5, "Cathodic Protection of Metals—Steel in Concrete Structure," allows extended depolarization for up to 72 h (Ref 191). Observation of several extended interruptions of reinforced-concrete CP systems has shown that depolarization continues for over 90 days (Fig. 42a; Ref 194).

Electrochemical Chloride Extraction (ECE) and Realkalization

Because the contamination of concrete by chloride ions is often the cause of corrosion in reinforced structures, it is natural that solutions were sought to prevent chloride ion contamination from occurring. For structures that were already contaminated with chloride ions, it was also reasonable that researchers would investigate how to remove these troublesome ions. In the 1970s, the FHWA funded two studies on removing chloride ions from chloride-contaminated reinforced-concrete structures (Ref 212, 213). Additional research by a private Norwegian company led to several patents, including ones in North America (Ref 214–216). The Strategic Highway Research Program (SHRP) also investigated the ECE technique (Ref 217). Field data indicate the technique is able to stop corrosion for 5 to 10 years.

Fig. 45 Directly applied thermal-sprayed zinc sacrificial cathodic protection system protecting both exposed and embedded reinforcement

Fig. 46 Cross sections of coated concrete. (a) Proper surface preparation where most of the contact between the coating and the concrete is with the cement phase. (b) Improper surface preparation with too much contact between the coating and the nonconductive coarse aggregate

ECE and Realkalization Theory. As discussed earlier, chloride ions migrate toward the anode. The ECE process is based on the fact that anions, like chloride, migrate to the anode when a direct current is passed through an electrolyte. Hydroxyl ions are the only other mobile anion present in quantity in chloride-contaminated concrete. To balance the charge transfer occurring in ECE (and in CP), cations migrate to the cathode, the reinforcement. In chloride-contaminated concrete, these will be sodium, potassium, and calcium. The amount of current that each ion carries depends on its charge, its concentration, and its mobility in the cement pore structure. Temperature will also play a role.

The ECE works by removal of chloride ions. How alkalinity is restored, although essentially the same process, is a bit more complex. At the surface of the steel (the cathode), two reduction reactions typically take place:

Both of these reactions produce hydroxyl ions, OH^- , which will increase the pH at the reinforcement surface. Oxygen availability is limited in concrete, which slows the progress of Eq 16. The current densities employed with ECE/realkalization are 100 to 500 times the current densities applied in CP systems. Most of the current collected on the reinforcement at ECE/realkalization current densities does so through the reduction of water (Eq 17). This process generates hydrogen gas and must be carefully considered if high-strength steels, such as those commonly used in prestressed concrete, are present in the candidate structure.

Evaluation of Candidate Structures. Successful application of ECE or realkalization depends on an accurate understanding of several concrete characteristics. Overall circuit resistance impacts the current output through Ohm's law, $I = E/R$. The concrete resistivity and cover depth over the reinforcement impact circuit resistance. A high degree of electrical continuity throughout the reinforcement matrix should also be confirmed.

Another concern with the application of ECE or realkalization is that the process can cause reaction with alkali-sensitive aggregate when present. Use of additives to the electrolyte, such as lithium borate, can reduce or avoid problems with alkali-reactive aggregate.

Preliminary investigations should confirm the availability of utilities (power and water) at the site. Also, because the temporary anodes may be in place for periods of four to eight weeks, the impact of that presence on other activities in the vicinity and the security of the system should be considered.

Application of ECE/Realkalization. If the reader is interested in applying ECE and realkalization technology, it is suggested that they review the SHRP publication (Ref 217) and the

NACE International state-of-the-art report on ECE (Ref 218).

Repairs. As with CP, necessary repairs are made to the structure prior to commencing the ECE/realkalization process. Likewise, repair materials employed are cementitious, and shrinkage and/or resistivity requirements should be specified as is appropriate.

Anode Electrolyte. The anodes used for ECE and realkalization are bedded in a temporary electrolyte. Numerous electrolytic solutions have been used. The most commonly used electrolytes are potable water and saturated lime water (calcium hydroxide). In situations where reaction with alkali-sensitive aggregate is possible, lithium bromate can be added to the solution. Lithium electrolytes are, however, expensive both to purchase and to dispose.

Anode reactions that can occur include:

Equation 18 will tend to make the electrolyte acidic. The reaction in Eq 19 shows the evolution of chlorine gas. If the electrolyte pH is allowed to drop below 4, significant amounts of chlorine gas can be generated. This could present health and safety issues. It is common practice to maintain the electrolyte pH to levels above 7 to minimize chlorine generation.

Catalyzed titanium is often used as an anode material for ECE and realkalization. It has the advantage of not corroding.

Steel anodes have a price advantage, but they are not inert. The corrosion of steel anodes minimizes electrolyte acidification and chlorine generation. However, the steel corrosion can produce rust stains on the concrete surface.

Electrolyte Medium. Given that the chloride-contaminated structure likely includes decks, soffits, and vertical surfaces, it is necessary to confine the electrolyte in a different way. For the topside of a deck, a simple dam can confine the electrolyte. For columns, a surface-mounted tank can be used. For vertical surfaces, cellulose fiber (e.g., used newspapers) can be used to formulate a spray-on electrolyte. Felt mats are also employed. After the electrolyte medium is placed, it is charged with the selected anode electrolyte.

Current Application. After repairs, verification of reinforcement continuity, and installation of the temporary anodes, anode electrolyte, and electrolyte medium, the transformer/rectifier that powers the system is energized. The initial voltage typically is slowly brought up to produce an initial current level of 1.0 A/m^2 (0.1 A/ft^2). The maximum system output voltage is kept below 50 V for safety reasons. The concrete resistivity often will drop as the concrete gets wet. Maximum current outputs are generally kept at values less than 2.0 A/m^2 (0.2 A/ft^2) of concrete surface, or less than 5.0 A/m^2 (0.5 A/ft^2) of steel surface. The transformer/rectifier units employed often provide both voltage and current regulation.

Corrosion in Commercial Aviation

Alain Adjorlolo, The Boeing Company

THE COMBINED SHARE of composite materials and titanium alloys in commercial aircraft structure has steadily increased at the expense of aluminum, the major material in use (by weight) and one that is corrosion susceptible (Fig. 1). The susceptibility of aluminum to corrosion and its wide application in the airplane structure have driven incremental and cumulative corrosion-control improvements over many years of airplane design. Boeing's newest commercial aircraft, the 787, will use significantly less aluminum. This choice is already causing changes in design and manufacture for corrosion prevention.

Corrosion control has been an integral part of the design and manufacture of commercial aircraft ever since corrosion-susceptible, high-strength or high-toughness aluminum alloys and steels became the design materials of choice. As commercial aircraft age in service, the structures experience many forms of corrosion, dependent on the alloy and temper, the finish, the assembly design and location on the airplane, the drainage, and the internal and external environments. Unattended, these may become serious airworthiness issues. In the United States, the Federal Aviation Administration (FAA) requires that the manufacturer "... show that catastrophic failure due to fatigue, corrosion or accidental damage, will be avoided throughout the operational life of the airplane ..." [Title 14—Code of Federal Regulations, Section

25.571], or that the airline operator have a plan to address corrosion problems and reduce their severity between inspections. "Each certificate holder is primarily responsible for the airworthiness of its aircraft ... the performance of the maintenance ... in accordance with its manual and the regulations ..." [Title 14—Code of Federal Regulations, Section 121.363]. The manual refers to the maintenance plan for the airplane, which is approved by the regulatory authority to ensure compliance with the "regulations." The manufacturer, the airline industry, and the regulatory authority act together to create conditions for continued airworthiness of all airplanes.

This article surveys forms of corrosion encountered in commercial airplanes, the factors that are important to design for corrosion prevention, some important lessons learned from 40 years of commercial jet airplane service history, and how corrosion data are collected. This article also provides an overview of the implementation and evolution of airline corrosion prevention and control programs (CPCPs) and directions being considered in the design for corrosion prevention of newer airplanes.

Corrosion Basics

When aluminum corrodes in an aqueous environment, its ions are liberated into the

environment at anodic sites and it is said to be oxidized.

At anodic sites (dissolution or oxidation):

Simultaneously, excess electrons left behind at anodes travel to adjacent cathodic sites, where they are absorbed by some species in the environment. The species of interest in corrosion in natural environments is oxygen, which combines with water in acquiring the electrons generated in the reaction shown in Eq 1 through the oxygen reduction reaction.

At the cathodic sites (reduction in aerated environments):

However, in the absence of oxygen water reduction takes place (reduction in nonaerated environment):

The corroding metal itself provides a path for electron transfer from anodes to cathodes, while the moisture on the surface provides the medium for the migration of ionic charges (from cathodes to anodes for negative ions, and anode to cathode for positive ions), completing the electrical circuit.

Whether or not oxygen is present, the net effect is that cathodic locations become increasingly alkaline. The presence of soluble salts introduces negative ions, which increase the ionic conductivity of the moist environment and thus allow reduction reactions to occur further away from the anode. In addition, they may render the environment more aggressive toward aluminum in specific ways. For example, the effect of ever-present chloride ions is to attract positive hydrogen ions at the anode. Hydrolysis of metal chlorides thus formed increases the acidity of the anode environment. Because aluminum and its alloys corrode at high rates in both acid and alkaline environments, the simultaneous increase in acidity at the anode and corresponding increase in alkalinity at the cathode lead progressively to more corrosive conditions alloys. On mating surfaces, evidence suggests that the presence of carbonate ions affect the morphology of the corroded surface (Ref 1).

Fig. 1 Material usage in commercial airplane construction

Commonly Observed Forms of Airplane Corrosion

The general mechanism described previously gives rise to these most commonly observed forms of corrosion in commercial aviation (Ref 2):

- General corrosion
- Exfoliation corrosion
- Pitting corrosion
- Microbiologically induced corrosion
- Galvanic corrosion
- Filiform corrosion
- Crevice corrosion
- Stress-corrosion cracking (SCC)
- Fretting and other types of corrosion wear

General corrosion is corrosion that is upon large surfaces of the material and that results in the overall thinning of the structure. It is the result of shifting anodes and cathodes on a metal surface. This form of corrosion has been observed particularly between disbonded aluminum skins and the interior or exterior fuselage belly skins.

Exfoliation corrosion is the leafing of rolled or extruded forms of aluminum alloys (Fig. 2a). Corrosion starts at an exposed end grain and proceeds through multiple parallel paths perpendicular to the dimension that is reduced in the forming process (short transverse direction). This form of corrosion is observed wherever the aluminum product forms listed previously are used, that is, wing and empennage (tail) skins, and wing, fuselage, and empennage stringers and chords.

Pitting is an acute perforation of the alloy. This form of corrosion is observed in all aluminum product forms used for fuselage skin, webs, and bulkheads. It is also observed on steels used in landing-gear and flight-control components. Pits are stress raisers and initiation sites for fatigue or stress-corrosion crack propagation.

Microbiologically induced corrosion manifests itself as pitting or intergranular corrosion. It is promoted by the presence of fungi (*Cladosporium resinae*) brought in by jet fuel. Figure 2(b) shows fungi responsible for microbial corrosion on a fuel tank access door. This form of corrosion is observed inboard of the wings, and is frequently observed on airplanes operated in warmer climates.

Crevice corrosion is corrosion that occurs inside crevices, tight joints, under absorbent materials, debris, or any recessed areas where stagnant conditions exist. Local oxygen depletion and acidification of the crevice environment give rise to an electrical potential difference with the region outside the crevice and leads to severe corrosion in the crevice. This form of corrosion is observed at unsealed joints and at joints where the fillet seal is broken. It is also observed on fuselage structures held in intimate contact with wet insulation blankets for extended periods of time. Crevice corrosion may be observed on

aluminum or stainless steel tubing under rubber clamps.

Stress-corrosion cracking is a brittle fracture of susceptible alloys occurring under load at stresses below the yield strength of the alloy. It results from the combination of tensile stress and environmental factors specific to the alloy. In commercial airplane operating environments, both aluminum and steels are susceptible. In aluminum alloys, cracking may result from wedging, that is, from tensile stresses caused by the expanded volume of corrosion products along grain boundaries, or from installation stresses. Alloy steels that are heat treated to strengths greater than 1520 MPa (220 ksi) are the most susceptible. Fracture occurs by a hydrogen embrittlement mechanism; that is, hydrogen produced through the reduction reaction (Eq 2b) diffuses to regions where subsurface residual stresses are present from service conditions. No SCC fractures have been observed with titanium components in service, although some alloy heat treat combinations of Ti-6Al-4V are susceptible to this form of damage.

Galvanic corrosion is the accelerated corrosion of a metal in electrical contact with another material that is more noble in the

galvanic series in the presence of moisture. Galvanic couples frequently encountered in commercial aviation are: titanium-aluminum, carbon fiber reinforced plastic (CFRP)-aluminum, aluminum-nickel bronze (Fig. 2c, 2d) and corrosion-resistant steel (CRES)-aluminum. Galvanic couples may exist between exposed cut edges of CFRP and aluminum. Figure 3 shows major galvanic groupings of alloys used in airplane design. Galvanic corrosion is also observed on stainless steel blind rivets, and alloy steel fasteners and clipnuts after their cadmium plating has worn away.

Filiform corrosion is surface corrosion that develops as wormlike filaments. These filaments grow under protective coatings and typically radiate out from fastener heads and skin edges. The head of the filament is the active corroding end and is acidic, while the tail is alkaline and filled with hydrated aluminum oxide.

Fretting and other wear-related forms of corrosion damage result from the synergistic effects between corrosion and wear. Fretting corrosion occurs when corrosion is associated with relative motion of small amplitude between two metallic surfaces. Hard abrasive particles break off from oxide corrosion products and

Fig. 2 Forms of corrosion in aircraft. (a) Exfoliation corrosion. (b) Microbiologically induced corrosion on fuel tank access door. (c) (d) Galvanic corrosion under aluminum-nickel bronze bushing

abrade the metal, maintaining fresh surface for further corrosion. Fretting is often found on fuel tank access doors.

Contact fatigue is an important form of damage on surfaces that experience moderate to high bearing stresses: rolling surfaces of flap tracks, flap carriage components journals, pins, and bearings. Undercutting of the plating by contact fatigue is often seen on chrome plated surfaces resulting in steel corrosion, as seen on the aft journal of a 747-400 flap carriage (Fig. 4).

Factors Influencing Airplane Corrosion

Each of the corrosion forms described can be the cause of major structural airworthiness issues. Each one of the effects is in direct relation to the structural design, to corrosion susceptibilities introduced during manufacturing, to operational environments (both internal and

external), to aircraft use, and to maintenance practices, which vary from operator to operator. Figure 5 summarizes these factors from the manufacturing perspective.

Design Factors

Improving the corrosion resistance of commercial aircraft structures has resulted from improvements made in these areas of design:

- Materials selection
- Protective finish systems selection
- Drainage
- Sealing improvements to eliminate crevices
- Use of corrosion inhibiting compounds
- Maintenance access

Materials Selection. An important goal of material selection is to ensure the use of inherently more corrosion-resistant materials.

Aluminum Alloys. For aluminum alloys, which are continuously developed to improve

structural performance and life-cycle cost (Ref 3), the trend has been to increase the use of overaged rather than peak-aged tempers. Several stress-corrosion fractures of 7079-T6 aluminum alloy in the late 1960s to early 1970s led to their replacement with 7075-T73, which has better corrosion resistance and a crack growth rate at least 2 orders of magnitude lower. Alloy 7178-T6 was also replaced because of low stress-corrosion resistance. The current choices in aluminum alloys for applications requiring higher strength with improved stress-corrosion and exfoliation resistance are overaged 7050, 7150, and 7055 plates and extrusions for upper wing skin, and 2324-T39 or 2024-T39 plates alloys for the lower wing skins. Clad 2024-T3/2524-T3 sheets or 2024-T351/2524-T351 plates are used on the pressurized fuselage. Cladding on the exterior skin of fuselage 2xxx series and 7xxx series alloys, which consists of 1230 and 7032 respectively, is provided for increased corrosion resistance. 2xxx-T3x alloys have relatively low exfoliation and stress-corrosion cracking resistance and therefore must be very well protected. The chemical-milled or machined surfaces of 2024-T351 clad aluminum plate used for bilge skin has proven to be a corrosion concern, regardless whether the milled cladding is internal, as in the 747-400 (Fig. 6), or external, as in the 777 (Fig. 7). Figure 7 shows how susceptibility to corrosion increases once the pure aluminum cladding is removed.

Steels and Other Metallic Materials. During the late 1960s to early 1970s, multiple failures in service of H-11 alloy steel bolts by stress-corrosion cracking led to their replacement throughout the entire Boeing fleet. Other steels no longer used because of their SCC susceptibility include PH 13-8Mo at strengths above 1520 MPa (220 ksi), 17-7PH, and maraging steels. For high-strength steels (1520 MPa and above), current designs use vacuum arc remelted and grain-refined AISI 4340M or 300M material for reduced susceptibility to hydrogen embrittlement in plating solutions, and to stress-corrosion cracking by the hydrogen embrittlement mechanism in service. The improved

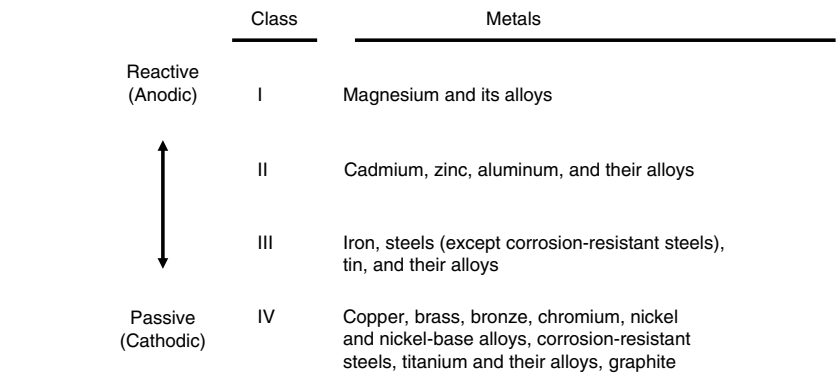

Fig. 3 Galvanic grouping of metals and alloys commonly used in commercial airplane design

Fig. 4 Chrome plating wear and corrosion of steel on a 747 flap carriage journal. The bottom view shows missing chromium plating and corroded journal.

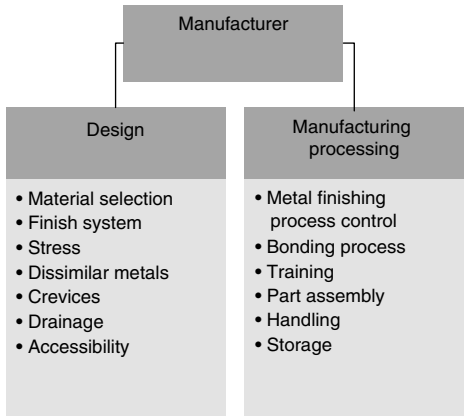

Fig. 5 Manufacturing factors contributing to corrosion

performance is the result of improved transverse ductility and toughness, which raises SCC resistance. Nevertheless, the alloy remains susceptible to corrosion and pitting. Corrosion pits can act as stress risers and lead to fractures. Some stress-corrosion fractures of high strength alloy steels have been observed in a few instances, including the bolt holes of the 767 main landing gear aft trunnion (Fig. 8). Alloy 9Ni-4Co-0.3C steels were used for engine mounts because of their good heat resistance combined with good stress-corrosion resistance. However, because of repeated corrosion from chipped finish, nickel alloy 718 or titanium is now preferred. The general trend is to eliminate corrosion-prone materials from design, such as increasing the use of corrosion-resistant steels (CRES) to replace low-alloy steels. To that end, nonferrous materials such as magnesium and its alloys are no longer used despite their weight benefit. Also, interest is being shown in Custom 465, a high-strength stainless steel. Despite its high cost, it is finding applications in trailing-edge links and flap track, and torque tube fittings in future programs, including the 787.

Protective Finishes—Organic and Inorganic. Protective finishes provide corrosion resistance, wear and abrasion resistance, and improved appearance. In combination with selected alloys, protective finish systems are subjected to extensive testing using industry standards. A list of standards and approaches to testing for corrosion protection for application to commercial aircraft design are described elsewhere (Ref 4).

For corrosion protection, the system consists of an inorganic coating, which serves as surface preparation, and one or more coats of an organic finish. For all exterior aerodynamic aluminum surfaces, the finish systems include chromate conversion coating, filiform corrosion-resistant primer, and polyurethane enamel as topcoat. For interior aluminum structures, it consists of chromate conversion coating or anodize, solvent-resistant chromate epoxy primer prior to assembly, and an additional coat of primer after assembly (Fig. 9). An integral fuel tank primer designed to resist the growth of fungi is used inside the wing. For aluminum parts that are to be bonded, the system consists of phosphoric acid anodize and a chromate bonding primer prior to assembly bonding. Corrosion protection of alloy steels components is provided by cadmium plating and chromate primer. Additionally, these components are topcoated with polyurethane enamel paint when used externally. Corrosion-resistant steels alloys are also cadmium plated prior to priming when galvanic compatibility with aluminum is required. Other corrosion-resistant materials such as titanium and nickel alloys may be left bare or painted to improve the appearance of the part. However, they are always painted to prevent galvanic corrosion resulting from contact with dissimilar metals when they are part of an assembly that includes aluminum alloys. To prevent galvanic corrosion of aluminum in assemblies with CFRP, the surfaces must

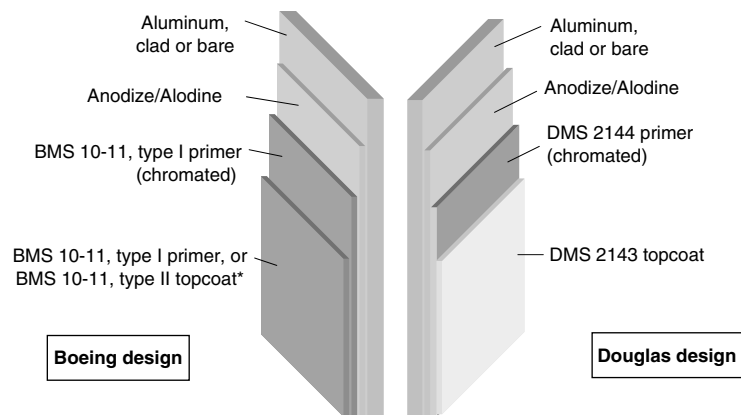

Fig. 9 Design finishes for all interior aluminum structures

have a cocured fiberglass ply, polyvinyl fluoride film, or be primed and topcoated as shown in Fig. 16.

Wear and abrasion resistance is provided to aluminum by hard anodize coatings. On steels, chromium plating is used. Macrocracking of chromium plating, and undercutting from corrosion in service (Fig. 4) is leading to gradual replacement with thermal spray coatings in selected applications. Unlike chromium plating, these may be applied to titanium alloys, allowing their use in wear applications. Initially, thermal spray WC-Co coatings were used. These have been replaced with more corrosion- and wear-resistant WC-Co-Cr coatings because of fretting and sliding wear issues experienced by WC-Co on seal surfaces.

Environmental Challenges. The aerospace finishing industry is increasingly being chal-

lenged by environmental pressures to limit the use of cadmium and chromium, materials on which current corrosion performance standards are based. Progress has been made in finding equivalent replacements in some areas. At Boeing, thermal sprayed WC-Co-Cr is gradually replacing chromium plating on all steels, and zinc-nickel alloy plating is replacing cadmium on all steels except on those with strength greater than 1520 MPa (220 ksi). However, proposed OSHA rules for an 8 h time-weighted average permissible exposure limit of one microgram of Cr(VI) per cubic meter of air ($1 \mu\text{g}/\text{m}^3$) for all Cr(VI) compounds (Ref 5) represent a significant challenge since chromates, which are used as corrosion inhibitors in primers, remain unsurpassed in their ability to protect aluminum against corrosion. Passage of this rule will require considerable adjustments industrywide.

Airplane Drainage. Fleet history indicates that corrosion is most often found at joints and pockets, under debris, wherever moisture traps exist, as shown in Fig. 10. This may be exacerbated by a design that does not provide adequate drain holes, or by maintenance practices that block drain holes or fail to open clogged ones as shown in Fig. 11. A complete and effective drainage system consisting of drain holes, tubes, where necessary, and drain valves must be part of the design. The current standard is to provide drain paths through $\frac{3}{8}$ in. minimum diam or 0.11 in.² minimum area holes, observing airplane angle with the horizontal when on the ground, to allow cross drainage. Holes or drain valves must also be provided at low points of the fuselage and wing.

Pressurized fuselage drain valves are spring loaded to close in flight and open on the ground.

Fig. 10 Fuselage corrosion locations learned from airplanes in service. (a) Upper and lower lobe. (b) Lower section of fuselage. BL 0 is the lowest longitudinal line of the fuselage (butt line). (c) Aft and wing

Enough of these drain valves must be provided to drain an estimated maximum amount of condensed moisture between landing and takeoff. Figure 12 shows typical locations of drain holes and a sketch of a fuselage drain valve. The drainage system is typically validated with the first airplane built and appropriate modifications made to address areas where moisture accumulation is found.

Sealants and Corrosion-Inhibiting Compounds (CICs). The use of sealants and corrosion-inhibiting compounds to keep moisture out of metallic joints has increased dramatically in recent years. Polysulfide sealants applied to mating (faying) surfaces keep moisture out of major assembly joints, such as wing chord to spar (Fig. 13), fuselage lap joints, and fuselage skin to stringer. In fact, this use of faying surface sealant has dramatically reduced corrosion of the outer wing at wing front and rear spar locations. The seriousness of such findings cannot be overstated as the corrosion may be impossible to detect until it exceeds limits allowed by design (Fig. 14). On similar metal contacts, for example, aluminum-aluminum or aluminum-cadmium plated steel, sealants prevent moisture entry and thus prevent crevice corrosion. Fastener holes are a major moisture path in permanently fastened installations. All exterior fasteners through structures required to sustain flight and ground loads and installations involving the stacking of different alloys are installed wet with sealant in order to block moisture path to mating surfaces.

Organic corrosion-inhibiting or moisture-displacing compounds are sucked by capillary force into unsealed joints to displace any moisture that may be present. Originally applied to structural joints, their use has expanded to open surfaces, driven in large part by airline maintenance, because they do not require disassembly of structural joints and often protect the finish against rapid deterioration from environmental exposure.

Sealant and CIC Use. The passenger floor structures have been chronic corrosion areas for Boeing 7xx series airplanes at "wet" locations, such as under galleys, lavatory, and entryways (Fig. 15). Here the improved use of sealant and CICs is preventing corrosion. Today (2006), areas under passenger entryways, and areas

extending 20 in. beyond galley and lavatory footprints, floor structures are covered with CIC. Floor panels are attached to the structure with plastic clipnuts, and the panel joints are sealed and overlaid with durable polyurethane seam tape. The entire floor is then covered with larger sections of polyurethane tape (Fig. 16). This design effectively prevents moisture ingress to the floor structure. The improved sealing avoids the more costly, but certainly more durable solution, implemented on the 777 airplanes with the use CFRP floor beams and titanium seat tracks, materials that do not corrode.

Special Assembly Consideration: CFRP-Aluminum Joints. Nowhere is the risk of corrosion greater than with assemblies involving CFRP and aluminum, materials at opposite poles of the galvanic chart (Fig. 3). Graphite fibers are excellent electrical conductors, do not corrode, and act as cathodes when attached to aluminum. Preventing severe corrosion of any attached aluminum structure involves the use of sealant to block all moisture paths, including fastener holes. It is also as important to ensure that cut edges, where graphite fibers are exposed, are sealed (Fig. 17).

Accessibility. Designing readily accessible structures is an important part of corrosion prevention. Accessibility is provided to allow easy visual inspection and repair of major structural components. The design must provide removal panels and access doors to serve that purpose.

Manufacturing Factors

Minimizing defects, and finding and correcting any that occur during airplane manufacture, is an important step in corrosion control.

Assembly Defect Control. Defects introduced during the assembly of the airplane, may

Fig. 15 Aluminum floor structure corrosion in a 767 at forward entry door

become initiation sites for corrosion, and must be avoided. If this is not possible, mitigating measures are often part of the design in the form of drawing notes, for example:

- Drain holes provided between detail parts of an assembly may occasionally be accidentally plugged during manufacturing with sealants. A note to remove excess sealant to avoid blocking a moisture path may be needed.
- Scratches may be introduced in the protective finish during fastener installation. Finish touch-up after assembly is required per design.
- Loss of paint adhesion due to contamination of surfaces to be painted. This discrepancy may be detected during fastener assembly, requiring a local refinishing. In the example shown in Fig. 18, undetected silicone contamination during the fabrication process and constant moisture exposure in service caused a loss of primer adhesion in a 747-400 airplane bilge.

Process Controls. Testing and process control are used to assess and avoid delayed fractures that can be caused by the manufacturing process. Cold bonding of lap joints was eliminated as a process in 1972 following significant bondline corrosion problems observed on Boeing airplanes built in the early 1970s. These can now be avoided with strict controls of the bonding process, with the development of phosphoric acid anodizing, and strict process controls including a wedge test (Ref 4) to assess bond quality. Stress-corrosion cracking or hydrogen embrittlement in high-strength steels are routinely avoided with process controls that

periodically assess embrittling conditions in process solutions. Part handling and assembly may create conditions where corrosion may be initiated in service. These must be recognized and addressed with adequate training/certification of inspection personnel and quality-control procedures.

In order to increase airplane structure durability and avoid catastrophic accident with corrosion as its root cause, commercial airplanes design and manufacturing have exploited improvements in materials and finish systems and sealing methods, expanded CIC use, improved access, and implemented better manufacturing controls. The resulting increase in value achieved with a more corrosion-resistant airframe can be maintained if operational factors leading to the deterioration of the structure are understood and adequately addressed.

Service-Related Factors

This section surveys factors responsible for airplane corrosion in service. The deterioration of the airplane structure from corrosion in service is the result of interaction with the airplane operating environment. Two types of aircraft environments should be distinguished: internal and external environments. Internal environments affect the interior fuselage, while the exterior environments affect all exterior structures including wing leading and trailing edge cavities, nose and main landing gear cavities, and nonpressurized fuselage tail section.

Internal Environments

The internal environment of the airplane fuselage contains various fluids from these sources:

- Condensation on internal surfaces
- Fluid spills in cargo compartments
- Toilet and galley leakage
- Wet insulation blankets in contact with structure
- Rainwater

Condensation. Moisture is generated inside the airplane cabin because of passenger respiration and perspiration. Condensation is heavily

influenced by aircraft loads factors (the percent of seats occupied on any flight), and airplane utilization rates (the number of flight cycles or hours accumulated per day). Most of this humidity collects on the fuselage skin as ice during cruise and thaws during descent. The time of wetness on long-range flights differs from short-stop flights. On longer-range flights moisture exists as ice much longer than as liquid. Because the converse is true for short-range flights, corrosion may be more of a problem on airplanes operated on short-haul flights at high utilization rates.

Cargo and Other Accidental Spills. In addition to being the collection zone for all condensation on the airplane, the structure below the cargo floor, or bilge, may be exposed to a variety of fluid spills with different levels of aggressiveness. They are direct consequence of transported cargo: live animals, fish, flowers, and chemicals. Despite measures put in place to control spills (e.g., special containers for the transport of fish), such spills do occur. On occasion, an airplane may be accidentally exposed to unique environments, such as hangar fire suppression systems, deluging the aircraft with fire-extinguishing foam while all airplane doors are open.

Lavatories and Galley Leakage. Older model lavatories were bolted directly to the floor structure. More recent airplane models have adopted vacuum toilets and self-contained lavatories. While this has reduced the amount of water spills from lavatories, leakage still occurs and seeps through floor panel joints onto the floor structure. These spills are often the source of corrosion of the floor structure under galleys and lavatories

Rainwater. Entry door locations are exposed to rain. Entry doors, similarly to galleys and lavatories, are also designated as “wet areas” for the purpose of designing the passenger floor.

External Operating Environment and Utilization

Factors that affect corrosion in external environment are:

- Geographic areas at or near coastal or industrial environment
- Flight regime

- Volcanic ash
- Airplane utilization
- Runway deicers

Significant amounts of moisture can accumulate on external surfaces of airplanes. Of particular importance, external surfaces accumulate aggressive species found in industrial pollutants, salt aerosols, volcanic ash (SO_2 , Cl^- , H_2SO_4 droplets, etc.).

While the corrosion concerns due to high humidity, temperatures, and pollutants have always been known to airline operators, the increasing use of potassium or sodium formate/acetate as runway deicers at airports in countries with colder climates is more recent as some airport authorities have replaced glycol or urea-based runway deicers with potassium formate or acetate for environmental reasons. This concern has been greatest for Boeing 737-600/700/800/900 operators with airplanes flying into airports where these deicers are used. In contrast with other airplane models, electrical connectors located in the landing gear wheel well may be splashed by runway fluids because of their proximity to the ground. Corrosion of connector pins and the resulting electrical connector failure was found serious enough to warrant regulatory action by the FAA (Ref 6).

Each airplane may be subject to a unique combination of the factors listed previously, which may lead to considerable variability in the onset and severity of corrosion depending where in the world it normally travels. However, among factors influencing corrosion of commercial airplanes one must also include maintenance practices and in-service finish deterioration. Figure 19 summarizes these factors from the operator perspective.

Maintenance Practices

Maintenance practices have a major impact on corrosion of the airplane structure. The goal of maintenance related to corrosion is to restore the level of protection to that of the as-designed airplane. However, the quality of corrosion-control measures implemented during maintenance can vary widely. This can range from

Fig. 17 Protecting aluminum against galvanic corrosion from contact with carbon fiber reinforced plastic (CFRP)

Fig. 18 Loss of paint adhesion caused by silicone contamination

barely adequate in some countries, to excellent. The training of maintenance workers may also be inadequate and the restoration of finishes may be left to low-skilled workers. In other instances, the level of cleanliness required of surfaces prior to the application of finishes may be inadequate. Maintenance tasks designed to reduce or prevent corrosion may not be adequately understood. On occasion, drain holes have been plugged with sealant during repairs.

Organic finish deterioration invariably occurs over the life of an airplane due to environmental exposure (Fig. 18). On exterior coatings, this deterioration manifests itself in the loss of flexibility, color, and gloss and requires repainting after 4 to 8 years. Deterioration of corrosion protective paints used in interior structures is very slow and may not be apparent over the entire life of the airplane. It is a general practice in the airline industry to apply corrosion-inhibiting compounds on most surfaces as frequently as necessary to increase the life of the paint.

Additionally, incidental finish damage and the restoration practices impact the appearance of corrosion. Deterioration that includes scratches and gouges in the protective finish may occur in service from debris. Scratches or gouges may be introduced in areas adjacent to repairs. It may be difficult, if not impossible, for maintenance crews to match the level of cleanliness for painting and sealing during maintenance repair that is achieved during manufacturing.

Areas of the airplane that are more likely to suffer from corrosion are often those that are more frequently accessed for inspection during maintenance. For instance, the floor structure in wet areas, which has benefited from improved sealing to make it more resistant to corrosion, is rarely found corroded during the first inspection,

but more often during the second, suggesting that the floor was not reinstalled as carefully as during original manufacture. While floor panel sealing has improved, inspection of the floor support structure has remained more frequent than may be necessary because of past corrosion problems.

Assessing Fleet Corrosion History

Most of the improvements made in the design and manufacture for corrosion prevention of commercial airplane are the result of corrosion data gathered from the in-service fleet. Several data-gathering tools have been used to assess the condition of airplanes in service:

- Aging fleet surveys
- Operator assistance requests messages (also known as “telex”)
- Corrosion Prevention and Control Program (CPCP) reports

Aging Fleet Surveys. Aircraft surveys are visits undertaken by the manufacturer at the operator’s maintenance base to assess the condition of the airplane structure with respect to corrosion and fatigue deterioration and to review maintenance practices for the fleet of similar models owned by the operator. These surveys provide valuable lessons about areas of chronic corrosion on the aging fleet or the efficacy of retrofit actions. Sometimes, survey trips are scheduled specifically to draw lessons to be used in the design of new or derivative models. Figure 20 shows a list of major corrosion locations discovered on the 767 airplanes during several 767 fleet surveys.

Operator and Maintenance Repair Organization (MRO) Messages. The repair of cor-

rosion damage that exceeds limits specified in the Structural Repair Manual (SRM) must be approved by the regulatory authority (FAA for U.S. registered airplanes). Airlines often direct requests to the manufacturer for assistance on engineered repairs. These requests provide detailed corrosion location and residual thicknesses after corrosion removal. For some locations, the number of such messages has grown steadily with the age of the fleet. Fuselage Sections 44 (over the wing) and 46 (aft fuselage) have been particularly hard hit on the first generation, or “classic,” fleet of 747 (Fig. 21a). In contrast, the request for corrosion repair assistance has remained constant for Sections 42 and 46 (Fig. 21b). As a result of this service history, drainage of the sloping pressure deck has been improved on the 747-400 and on the 777 airplanes. Sealing of the floor in areas in the wet areas of the 747-400 has also been improved as a result.

Corrosion Prevention and Control Program (CPCP) Reporting. The CPCP is one of several programs mandated by the FAA on all airplanes operated in the United States. It defines minimum requirements to address corrosion before it becomes an airworthiness concern. Under this program, operators are required to submit to the regulatory authority and the manufacturer a report for each severe corrosion finding (called a level 2 finding). The report contains the exact location of the corrosion, the probable causes of corrosion, and whether corrosion was caused by a unique event, such as an accidental spill, or by a condition that might exist on other airplanes in the operator’s fleet. The intent of the additional reporting to the manufacturer is to assess the effectiveness of the baseline CPCP in order to adjust it as necessary. Figure 22 shows a worldwide distribution of level 2 reports. This distribution may be inaccurate in describing the worldwide fleet status with respect to severe corrosion: they indicate a larger percentage of “level 2” corrosion in developed countries for all models. However, these reports have been valuable in helping the manufacturer identify chronic corrosion problems areas and underlying design weaknesses. It should be noted since 2002 that reporting to the manufacturer is no longer required. However, reporting to the FAA remains in effect as defined under Title 14—CFR Section 121.703.

Information from the sources listed previously has contributed greatly to increasing Boeing’s understanding of regions with chronic corrosion problems and their severity. This information has driven cumulative design improvements (Fig. 23). These have been incorporated into “Book 4—Design for Corrosion Prevention” used by Boeing-Puget Sound engineers as a guide for the design of new 7xx series airplane models or derivatives. Similarly, lessons learned for Douglas models and derivatives were incorporated into the Type Finish Specifications TF-109 (DC-9, MD80, MD90, Boeing 717) and TF-110 (DC-10/MD-11).

Airworthiness, Corrosion, and Maintenance

Many commercial aircraft are being operated well beyond their original economic design service objective (DSO), a minimum period of service during which the airplane structure is essentially free of detectable fatigue cracks. This practice will continue as long it is profitable to do so. However, since continued safe operation and prevention of accidental hull loss is the prime consideration, how corrosion is addressed as the airplane structure ages is of paramount importance.

Airworthiness defines the ability of an airplane to sustain all fail-safe design loads (limit loads) throughout its operational life without catastrophic failure. For continued air-

worthiness, it is now recognized that fail-safe design loads must be sustained in the presence of all damages that may occur in the airplane operating life, that is, accidental, fatigue, or corrosion damage, until such time when the damage is detected through inspection and repaired. This concept, known as damage tolerance, became the standard principle for establishing maintenance programs for all airplane models since 1979. All post-1979 models have included damage-tolerance principles in their design and incorporated them into their baseline maintenance programs.

The maintenance of earlier, fail-safe-designed, airplanes did not include provisions for multiple inspections of an airplane structure near or above the DSO before a crack reached its critical length. The application of

damage-tolerance principles to these older airplanes relied instead on data from extensive structural testing and tear-down. The required inspection methods and frequency were determined using linear elastic fracture mechanics analysis techniques relating detectable damage, damage growth, and critical damage size. These were published in a supplemental structural inspection document (SSID) for the detection of fatigue damage for each affected model.

Effect of Corrosion on Airworthiness. It was recognized at the outset of the SSID program development that uncontrolled corrosion could act synergistically with fatigue, resulting in faster crack initiation, unpredictable crack growth, and significant reduction in the damage detection period. Thus, for fatigue inspection frequencies to be valid, corrosion had to be detected early and treated quickly. Nevertheless, no industry-wide action was taken to mandate timely corrosion detection and repair, and it was left to the discretion of each airline operator to develop its own corrosion-prevention program.

The severe impact of unattended corrosion on airworthiness of a structure designed to carry a significant portion of pressure loads was dramatically demonstrated to the world with the explosive decompression of a 737 fuselage in 1988 (Ref 7). Several small fatigue cracks had grown and linked up in a disbanded and corroded fuselage lap joint. This event led the FAA to mandate aging airplane programs that included PCPC, SSID, mandatory service bulletin

modifications, and repair assessment programs for all older airplanes. Several airworthiness directives (ADs) were issued in 1990 for each older airplane model CPCP.

The ADs required that operators of older airplanes that did not have an effective corrosion-prevention program adopt a baseline CPCP as a supplement to their maintenance program. To ensure commonality of approach between airplane manufacturers, the baseline programs for each airplane were developed under an Airworthiness Assurance Working Group (AAWG) steering committee, and through structure task groups (STG) that included airplane manufacturers, operators, and the FAA. For Boeing aircraft, the mandate was applicable to pre-1979 airplanes and their derivatives, that is, 747-400 and 737-300/400/500. Because post-1979, "damage-tolerant" airplanes (757 and 767) incorporated into their maintenance program all recommended inspection tasks and intervals

for the aircraft components and structure, including corrosion tasks, an AD for implementation was not required. However, their CPCP remained separate from the structural inspection programs.

Maintaining airworthiness for older airplanes and earlier damage-tolerant ones meant conducting a variety of independently developed programs requiring multiple access and ground time for inspections that targeted the same structures. Airplanes certified in 1993 and later have a consolidated structural maintenance program, which provides a single opportunity to inspect for accidental, fatigue, and corrosion damage. This results in significant cost savings to operators. These consolidated programs were developed under a Maintenance Steering Group (MSG), using a methodology called MSG3-Rev 2 (Fig. 24). This methodology can be used for analysis of airplanes certified before 1993 (Ref 8) at the request of the airplane operator.

The approach and evolution of the CPCP program for all airplanes is reflected in Fig. 25.

See the article "Predictive Modeling of Structure Service Life," *ASM Handbook*, Volume 13A, 2003, for more on these design philosophies and fleet maintenance.

Corrosion prevention during maintenance is accomplished via observance of practices contained in CPCP documents for pre-1993 airplanes and consolidated maintenance documents for newer airplanes. The airplane structure is subdivided into primary structure, that is, structure required to sustain ground and flight loads, and secondary or principal structural element (PSEs). Principal elements are structural details or assemblies judged significant because their failure would result in the reduction of the airplane residual strength. Most primary structural elements and PSEs are in similar airplane zones and are grouped into corrosion tasks.

Inspection Methodology and Maintenance Decisions—Corrosion Prevention and Control Program. Maintaining the airworthiness of all aging aircraft structures regardless of when they were designed means adopting good maintenance practice and developing skills in the areas of corrosion detection and repair. The baseline CPCP contains minimum standards to maintain safety. The program defines:

- Corrosion levels
- Basic tasks
- Implementation age (I)
- Repeat interval (R)
- Mandatory reporting requirements for all severe corrosion (level 2 and 3) findings
- Periodic review of these reports by the STG to adjust the program, as necessary

Corrosion Level Determination. Three corrosion levels are defined, based on allowable damage and whether the corrosion is local or widespread. Allowable limits for each structure, that is, the maximum amount of material that may be removed from the structure by blend-out before its strength falls below ultimate design loads, are set during design and found in the Structural Repair Manual (SRM) for each airplane model. Local or widespread corrosion indicates whether corrosion is restricted to a single frame chord, stringer, stiffener, and skin not exceeding one stringer, frame or stiffener bay, or whether the corrosion involves two or more of these structures in adjacent locations (Fig. 26). A more complete description of the corrosion level assignments to corrosion findings is shown in Fig. 27:

- Level 1: Corrosion found between successive inspections that is within allowable limits
- Level 2: Corrosion found between successive inspections that exceeds allowable limits
- Level 3: Corrosion found during first or successive inspections that is determined by the operator to be an urgent airworthiness concern

Basic Tasks. The assignment of corrosion level is made following corrosion removal

Fig. 22 Percentage of in-service airplanes with CPCP reports of level 2 corrosion. Refer to Fig. 27

Fig. 23 Cumulative number of corrosion resistance improvements on the 747

and cleanup, or corrosion blend-out, which is necessary when corrosion is found. Most importantly, it is intended to trigger certain actions on the part of the operator to ensure that any subsequent finding on the same structure will be at level 1 or better, and to demonstrate compliance with the CPCP program. The set of required actions includes six tasks in each PSE zone:

- Ensuring adequate access through the removal of all systems equipment and interior furnishing

- Ensuring cleanliness of the structures to allow inspections
- Visual inspections, recognizing corrosion types and symptoms
- Performing the repairs, including complete corrosion removal and adequately restoring all protective finishes
- Clearing of blocked drainage paths
- Application of suitable water-displacing and corrosion-inhibiting compounds

Implementation Age and Repeat Inspection Interval. The basic tasks are to be accom-

plished at the implementation age (*I*) and each repeat interval (*R*). Values of *I* and *R* vary with the structure location, the airplane model, and are based on previous service history. For example, all 747 fuselage bilge structure must be inspected first after 6 years, with a repeat inspection every 4 years. By contrast, for the less corrosion susceptible fuselage crown *I* is 15 years and *R* is 8 years. The interior of the main wing inspection requirements are 20 years for *I* and 10 years for *R*. In contrast, the more corrosion-susceptible exterior leading edge wing are 6 years and 2 years, respectively. Figure 28 contrasts *I* and *R* values for the original 737 and 747, or “classic” airplanes, with their more modern derivatives showing that improved design of the derivatives airplanes often leads to relaxed initial inspection requirements.

Inspection Methods. Step 3 of the basic tasks instructs maintenance personnel to “visually inspect all PSEs and other structures listed in the baseline program from a distance considered necessary to detect early stages of corrosion, or indication of other discrepancies such as cracking.” Successful implementation of the program thus requires effective visual corrosion recognition and detection, in addition to repair and other prevention efforts.

If severe corrosion is found on a structure during CPCP inspections (namely, level 2 or 3), the operator is required to take appropriate measures. The CPCP program must be adjusted to reduce the severity of corrosion at the following inspection. Thus, an effective CPCP is one that controls corrosion of any PSE to level 1 or better between successive inspections. Figure 29 illustrates the fleet damage rate with and without an effective corrosion-prevention program. Without an effective corrosion program, maintenance costs resulting from the repairs of severe corrosion and fatigue damage escalate sooner in the life of the aircraft than DSO. With an effective corrosion program, the design economic life of the airplane may be fully realized. Program adjustments may be made to the basic tasks or to the repeat intervals to maintain airworthiness. Operators may escalate their programs by reducing the baseline inspection interval if unable to control corrosion. Conversely, they may request approval from the regulatory authority for “de-escalating” specific tasks if the corrosion history justifies it.

It has become clear in recent years that the CPCP may not have the full capability to detect corrosion that occurs between mating surfaces until it is made visible in its advanced stage through a severely bulging structure or hole punctured through the structure. Figure 14 shows corrosion through the wing front spar lower chord and web of a 747. In these cases, low-frequency eddy-current (LFEC) and ultrasonic inspection methods must supplement visual inspection, and additional adjustment to supplemental fatigue inspection must be made to account for cracking scenarios that

result from hidden corrosion (Ref 9). It should be noted that application of faying surface sealant, now required between major joints as

shown in Fig. 13 for the wing chord to web attachment, has significantly reduced these occurrences.

New Fleet Design: Establishing Rule-Based Corrosion Management Tools

The advent of airplanes in which the majority of structure is composites has created a need for a more methodical approach to manage galvanic

Corrosion severity relative to SRM allowable blend-out limits	Corrosion level for given extent and number of inspection intervals to reach given severity

coupling and assess the strategic value of eliminating aluminum in large areas to gain significant maintenance breakthroughs. Recent efforts at Boeing on the 787 have focused on each of these areas.

Managing Galvanic Coupling: The Corrosion Risk Assessment (CRA). Galvanic coupling of aluminum with CFRP across a broad range of parts and airplane locations is inevitable. On the 777, this was managed through the use of isolation practices summarized in Fig. 17 and required extreme attention to details by specialists. Carbon fiber reinforced plastic was primarily used on the horizontal and vertical stabilizers. This approach worked well because the applications were sufficiently limited to allow review of design details by these specialists. However, with airplanes such as the 787, the extent of galvanic CFRP-aluminum coupling use is such that reliance on specialists of different airframe sections to review all specific details is impractical in terms of cost and speed. Fortunately, efforts on the 777 have enabled the creation of CRA, an airplanewide evaluation process that can be used by designers to assess and manage risk.

The CRA considers parameters such as environment severity (determined by the location of the assembly on the airplane), the part protection scheme (applied finish, fasteners installation, and graphite cut-edge sealing, and isolation material), and the susceptibility of the protection scheme to damage. Taken together, these parameters define a corrosion risk for the assembly.

Assessing Strategic Value: The Rectification Impact Assessment (RIA). The ability to

further reduce maintenance costs on past airplanes was limited by their use of aluminum. Federal Aviation Administration mandated corrosion prevention and control programs (CPCPs) are required if any structurally significant items are made of aluminum. The frequency and costs of this inspection depend on the environment and service history of the airline. The expanded use of CFRP on airplanes such as the 787 now enables designers to consider the benefit of eliminating the remaining aluminum structure to achieve further savings in maintenance (CPCP), nonroutine inspections, and corrosion repair. The need for a system by which these decisions can be managed and uniformly made is addressed by the rectification impact assessment (RIA).

The RIA, in contrast to the CRA, recognizes that corrosion may nonetheless occur on any aluminum structure, including one that is a primary load path, due to a potential manufacturing defect, and such corrosion may result in maintenance repairs of great difficulty. The relative “pain” of having to perform these repairs is assessed by considering RIA parameters: corrosion detectability, reparability, and the impact or structural significance of the part. Naturally, a structurally significant assembly that is difficult to detect and repair increases the “pain and cost” of a nonroutine maintenance repair or rectification. A high corrosion-rectification risk indicates a “painful” repair.

To design for corrosion resistance and reduce corrosion-related maintenance costs, minimum thresholds of CRA and RIA are chosen based on the 40 year cumulative corrosion history of mostly aluminum airplanes. In order to use aluminum in a new design, these minimum threshold scores must be achieved.

New Airplane Maintenance

The expanded use of composite material in airplane design (Fig. 1) also provides opportunities for additional changes in approach to maintenance. A consolidated structural maintenance program covering accidental, fatigue, and corrosion damage will still exist for all metallic structures. However, with fatigue inspections of metallic materials starting at 100% of DSO instead of 75% of DSO as for previous airplane models, and the use of titanium alloys for improved corrosion resistance where minimum CRA and RIA thresholds are not met, airplanes such as the 787 are expected to significantly reduce maintenance costs compared to the aluminum airplane fleet.

Additional savings may be achieved with structural health maintenance using strain gages to monitor structural damage and determine which structures to inspect in the event of hard landing. Although it is farther in the future, in situ corrosion and humidity monitoring with optical fiber-based sensors may offer additional benefits (Ref 10). A system for the detection of humidity has been recently field tested

by a major U.S. airline in the bilge of a 767 airplane.

Conclusions. With more than 40 years of corrosion information accumulated on commercial airplanes in service, significant lessons have been learned. These lessons are being applied in the design of new and the next generation of commercial airplanes. Significant reduction in corrosion has been achieved with careful material selection, enhanced and strategically placed drainage, state-of-the-art primer, coatings, and enamels, systematic use of sealants to eliminate the presence of moisture entry into structural joints, and electrical isolation for CFRP-aluminum assemblies. Additionally, implementation of a self-adjusting CPCP allows operators to keep corrosion within the limits of applicability of damage-tolerant designs. For the next generation of carbon fiber reinforced plastic airplanes, a disciplined corrosion assessment purports to remove aluminum from areas where corrosion risk is too high and to improve the protection during design, further reducing maintenance costs.

Corrosion in Microelectronics

Jianhai Qiu, Nanyang Technological University, Singapore

TREMENDOUS TECHNOLOGICAL ADVANCES have been made in the microelectronics industry. From industrial control and telecommunications equipment to consumer digital electronics, the industry is driven by ever-increasing demands for performance, miniaturization, and low-cost reliability. The continued shrinkage of integrated circuit (IC) design, coupled with the need to integrate new materials for high-speed performance at low cost, continues to pose new challenges to reliability engineers.

In the early 1970s, IC failure rate in the range of 1000 to 2000 FIT (1 FIT is 1 in 1,000,000 failures per 1000 h) was considered acceptable. This was reduced to 100 FIT in the 1990s. By the year 2007, a failure rate of 0.1 FIT is expected (Ref 1). Increasingly, corrosion has become a significant reliability concern and has received considerable attention in the literature (Ref 2–15).

Common problems encountered with ICs and supporting microelectronic devices include (Ref 16):

- Galvanic corrosion
- Electrical short due to corrosion
- Increased contact resistance due to corrosion
- Degradation of organic surface coatings
- Swelling of materials due to moisture pickup
- Degradation of electrical and thermal properties in insulating materials
- Changes in mechanical properties (loss of strength)

Electronic materials are selected and optimized for their electronic, magnetic, and optical properties. Devices and components inevitably use dissimilar metals, for example, aluminum and gold at a bonding pad on an IC. Electrical bias is often present during operation. In the presence of moisture and contaminants, corrosion ensues. The extremely small physical dimensions make the devices and components even more susceptible to corrosion. A heat exchanger can still function with kilograms of metal loss due to corrosion, but an electronic device may fail after the loss of only one picogram. In heat exchangers, corrosion allowance or tolerance are built into the equipment, whereas in microelectronic devices and components, there is no corrosion allowance at all.

Common components susceptible to corrosion attack include IC chips, circuit boards, and associated components such as connectors, switches, and transformers. A video games vendor spent several thousand dollars per month on replacing corroded circuit boards. Consumer digital electronics such as digital cameras and hand phones may also suffer from severe corrosion attacks after use in outdoor environments. The accumulated corrosion at the connector of a digital camera over a few months' usage was sufficient to cause inconsistent battery operation and inaccurate indication of the need for battery recharging. Even the equipment built for corrosion testing and measurement is not immune to corrosion in the laboratory atmosphere. The electrode cable connecting a potentiostat became loose due to the corrosion, and alternating current impedance response and direct current polarization resistance were affected, with an error of 43% (Ref 17).

The fundamental principles of corrosion are detailed in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. Corrosion in microelectronics, as in other industries, is governed by the electrochemical principles for aqueous corrosion. There are, however, some characteristics unique to corrosion in microelectronics.

Characteristics of Corrosion in Microelectronics

The materials, the design, the package type, and the environment influence corrosion in microelectronics.

Materials selected for use in microelectronics are primarily based on their electrical, magnetic, and optical properties, ranging from noble metals such as gold and silver to more reactive metals such as aluminum and its alloys. Table 1 shows typical applications of conductors and contact materials (Ref 18). The functionality of devices requires extensive use of dissimilar-metal contacts. Galvanic corrosion, pitting in electrodeposits (Fig. 1), anodic corrosion (oxidation of a metal, such as aluminum, at the anode sites), and cathodic corrosion (attack on cathodically biased aluminum by a hydroxyl ion from cathodic reduction of oxygen or water) are direct consequences of the inherent multimetal system designs.

Design and Packaging. The submicron separation of metal lines on IC devices, the extremely thin and often porous gold and silver plating on substrates, and the extensive use of dissimilar metals make microelectronic devices and components extremely susceptible to

Table 1 Typical applications of conductors and contact materials

Material group	Alloys	Typical applications
Copper alloys	C11100, C19400, C10100, C19500, C10400	Lead materials, leadframes
Electroplated copper	...	Printed wiring
Beryllium-copper alloys	C17000, C17200, C17400	Contact springs
Brass alloys	C36000, C27000, C26000	Contact pins
Phosphor-bronze alloys	C51000, C52400	Contact pins
Electroplated gold	99.9Au-0.1Co; 99Au-1Co	Finish for contact surfaces
Gold alloy	99.99Au	Bond wires
Silver alloy	...	Contact materials in relays
Electroplated silver	...	Finish for high-frequency components
Tungsten	Tungsten powder/binder(a)	High-temperature cobalt-fired metallization
Molybdenum	Molybdenum or molybdenum/manganese powder/binder(a)	Co-fired metallization
Electroplated rhodium	...	Finish for mating contact surfaces; high-wear applications
Aluminum	Al-1Si; Al-1Mg	Bond wires, metal lines
Kovar	29Ni-17Co-54Fe	Pins for glass-sealed feed-through leadframes; glass-sealing applications
Alloy 42	42Ni-58Fe	Leadframes; brazed leads

corrosion. In order to minimize manufacturing cost, the design may use alternative processes and materials (e.g., gold interconnect layers replaced with aluminum alloy), with limited understanding of the possibility of corrosion during manufacturing processes and in service. Although rare, under favorable conditions, including the presence of an electrical bias, even noble metals such as gold will corrode actively. Polymers such as epoxy and silicone used in plastic packages are relatively permeable to water or moisture and other corrosive chemicals. Virtually all plastic-encapsulated packages are therefore susceptible to corrosion. Some flame

retardants such as bromine added to epoxy encapsulant can significantly accelerate corrosion (Ref 19). For hermetically sealed packages, the sealed-in moisture and contaminants are sometimes sufficient to cause corrosion of the exposed metals. The seals may also leak at edges or cracks.

The Environment. Microelectronic components and systems traditionally were found mostly indoors, and within packages or cabinets when used outdoors, and so they were sheltered from direct weathering agents such as sunlight and precipitation. Now, more are used outdoors, so if the enclosure is improperly designed, the corrosivity can increase due to elevated temperatures or humidity. The atmosphere to which a microelectronic component and package is exposed can vary from a purified and filtered indoor to an industrial or marine atmosphere in outdoor exposure.

to the deterioration of the material and its property” (Ref 20). Under this definition, reliability issues pertaining to humidity, contamination, temperature, and electrical bias are all within the domain of corrosion. Corrosion can originate from many sources during manufacturing, storage, shipping, and service. Moisture, temperature, contaminants, and electrical bias, either alone or in combination, often initiate or accelerate corrosion of many metals. The form and rate of corrosion are dependent on the materials, the fabrication and assembly processes, the design, the package type, and the environmental conditions. Figure 2 shows the common sources of corrosion in microelectronics.

Relative Humidity and Moisture. Air contains water vapor in addition to its major constituents of nitrogen and oxygen gases. At any given temperature, the amount of water contained in a unit volume of air (g/m^3) is referred to as the absolute humidity. The higher the air temperature, the more water it can contain. Relative humidity (RH) is the amount of moisture in the air (absolute humidity) compared with the maximum amount of moisture that the air can hold at the same temperature. Because warm air can hold more water than cool

Fig. 1 Pitting of electrodeposit on a copper leadframe

Common Sources of Corrosion

Corrosion is defined as “the chemical or electrochemical reaction between a material, usually a metal, and its environment that leads

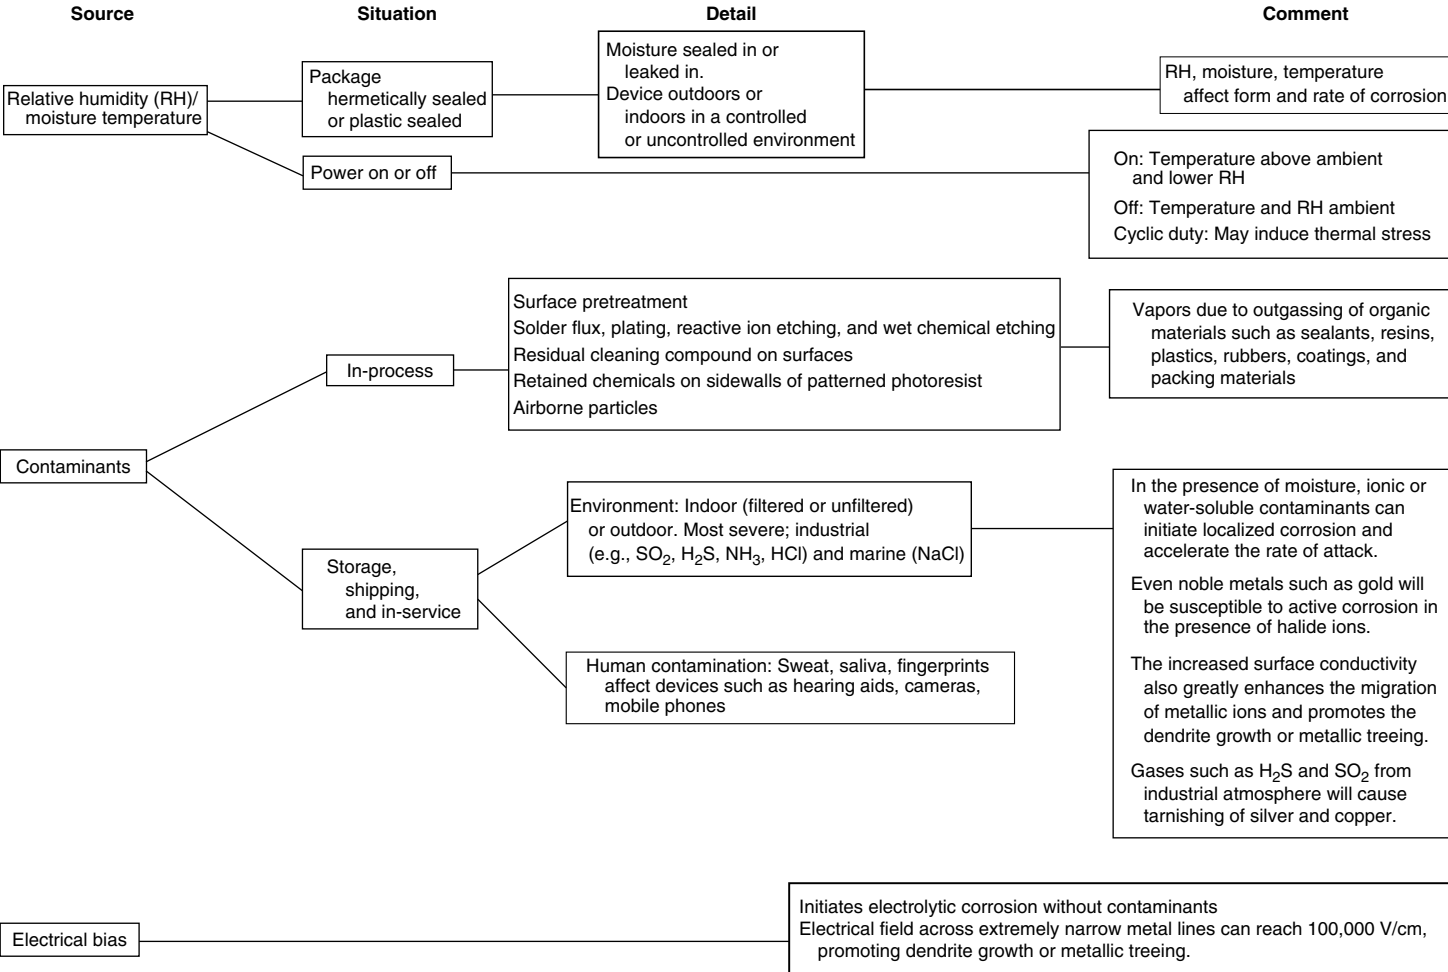

Fig. 2 Common sources of corrosion in microelectronics

air, there is less water in 20 °C (68 °F) air compared to 25 °C (77 °F) when they are both at 60% RH. There exists a critical RH above which significant corrosion takes place. Research (Ref 21) indicates that three monolayers of condensed water molecules are the absolute minimum amount of moisture that can raise the surface conductance to a significant level. As the thickness of the surface moisture film increases, the corrosion rate for most metals rises sharply, and a peak is observed at approximately 1 μm (0.04 mil) (Fig. 3). Further increases in moisture film thickness result in a reduction in the corrosion rate due to diffusion-controlled oxygen reduction. The corrosion rate levels off at a moisture film thickness above 1 mm (0.04 in.), which is equivalent to the total immersion condition.

In hermetically sealed packages, the sources of moisture include the sealed-in moisture and that which leaked in through cracks or edges. Polymer-encapsulated packages are permeable to moisture and other corrosive chemicals, such as SO_2 , H_2S , and NaCl , depending on the location and the nature of the exposure site. These corrosive chemicals, when dissolved in the moisture film, can increase the surface conductance, modify the pH of the electrolyte, and lead to accelerated corrosion attack on most metals.

Temperature. Dewpoint temperature, the temperature at which moisture will condense on a surface, is an important concept in corrosion. At the dewpoint temperature, the air immediately next to the surface is at 100% RH, and moisture cannot evaporate from the surface. When electronics are using power, the heat generated may be beneficial and raise the surface temperature (possibly above the dewpoint temperature) and lower the surface RH below the critical RH. This can reduce the corrosion rate. However, as the combination of ambient conditions and internal heating increases the surface temperature, the corrosion rate roughly doubles for every 10 °C (18 °F) rise in temperature. It

was calculated that at 70 °C (158 °F), without packaging, a bare aluminum bond pad (100 by 100 by 1 μm , or 4 by 4 by 0.04 mils) would be completely corroded within 67 h, and an interconnect segment (5 by 5 by 1 μm , or 0.2 by 0.2 by 0.04 mil) would be completely corroded within 10 min (Ref 23). The effect of temperature and RH on the mean time to failure has received considerable attention. Table 2 shows models proposed in the literature (Ref 24).

Contaminants that are of concern to microelectronics include ionic contaminants, corrosive gases, and vapors (Ref 6). Ionic contaminants or water-soluble salts have long been recognized to cause corrosion, particularly in the protective coatings industry. In microelectronics, the reliability hazard of ionic contaminants increases dramatically as the device size shrinks and the density increases. For example, a current of 10^{-13} A has no significant effect on standard circuit board conductor stripes operating for many years but will cause failure of a 0.1 μm (0.004 mil) wide conductor in less than 1 min. The ionic contaminants can either directly induce or indirectly assist the corrosion of metallic materials. For example, chloride is well recognized to cause breakdown of normally protective oxide films, leading to localized corrosion of both positively biased and negatively biased aluminum (Ref 30–32). Chloride is also involved in the formation of gold complex ions and can cause corrosion of gold conductors (Ref 33). Other ionic contaminants, when dissolved in the moisture film, increase the conductivity of the surface electrolyte and hence accelerate corrosion. Contamination may come from several sources, such as in-process contamination due to the presence of residual chemicals, storage- and shipping-related contamination, in-service contamination, and contamination due to human contact (Fig. 2).

In-Process Sources. Microelectronic systems are fabricated by a number of complex and often proprietary processes. Residual chemicals from processes can introduce significant

amounts of ionic contaminants. Solder fluxes, plating, and various etching processes may leave residual chemicals on the surfaces of metals or sidewalls of patterned photoresist. Microelectronic devices are particularly susceptible to fine airborne particles with aerodynamic diameters of 0.05–2 μm (0.002–0.08 mil) (Ref 34–36). These fine particles are rich in ammonium acid sulfate and are difficult to remove by filtration. See the article “Corrosion in Semiconductor Wafer Fabrication” in this Volume.

Storage and shipping of components, semifinished and finished devices, can lead to contamination by exposure to unregulated atmospheres. The devices are also subject to the fluctuation of ambient RH and temperature (Ref 8). Condensation of moisture and deposition of airborne particles can lead to localized corrosion, such as pitting and galvanic corrosion. Tarnishing of noble metals by corrosive gases, such as NH_3 , SO_x , and H_2S , are also encountered.

In-service microelectronic devices must withstand normal and abnormal conditions. Airborne particles have caused field failures in facilities such as telecommunication centers (Ref 37). Fires involving polyvinyl chloride cables and pipes release hydrogen chloride vapor that can pose serious reliability hazards. Graphitic carbon formed in fires can significantly increase the leakage current, because graphitic carbon is conductive even at low RH. In locations within 1 km (0.6 mile) from the coast, airborne chloride concentrations are sufficiently high to cause corrosion failures of electronic components. Circuit boards in radar systems, video game machines, and entertainment equipment are particularly susceptible to corrosion in the marine atmosphere, largely due to the high chloride contents and the high RH. For industrial-control electronics, the common atmospheric contaminants corrosive to components and ancillary equipment are given in Table 3 (Ref 38).

Human contamination is known to be a source of IC failures (Ref 11, 39). Throughout materials processing, device fabrication, assembly, shipping, installation, and operation, human contact, either direct or indirect, is inevitable. Body effluvia from perspiration, skin oil secretions, and coughs and sneezes contain significant amounts of chlorides and alkali ions that can induce or assist corrosion of most metals, including gold. Consider how a hearing aid is in direct contact with the human body. Perspiration (a source of chloride and humidity) and water splash can cause failures of the microelectronics if contamination is present and the packaging is not properly designed.

Electrical bias is present in all microelectronic active devices, and it is also one of the most important factors in corrosion failures. At the present time (2006), the conductor width and separation on ICs has reached submicron level. The electrical fields across these extremely narrow metal lines can exceed 100,000 V/cm. A few monolayers of adsorbed water may increase the surface conductivity by several orders of

Table 3 Common industrial pollutants corrosive to microelectronics

Pollutant	Sources	Susceptible metals
Sulfur dioxide (SO ₂)	Fossil fuel combustion, petrochemical industries, pulp and paper industry, metal-producing industry	Most metals
Nitrogen dioxide (NO ₂)	Auto and truck emissions, fossil fuel combustion, various industries	Copper, brass, synergistic with SO ₂
Hydrogen sulfide (H ₂ S)	Pulp and paper industries, chemical industry, sewage plants, landfills, oil refineries, animal shelters, volcanic activity, swamp areas, marine tidal areas	All copper- and silver-base metals
Chlorine (Cl ₂) (gas most important)	Bleaching plants in industries, metal production, polyvinyl chloride plants, cleaning agents	Most metals synergistic with other pollutants
Ammonia and its salts (NH ₃ and NH ₄ ⁺)	Fertilizer, animal and human activity, detergents	All copper-base alloys, nickel, silver
Chloride (Cl ⁻)	Sea salt mist, road salt areas	Most metals
Soot (C)	Combustion, auto and truck emissions, steel production	Synergistic with other pollutants; provides cathodic sites for most metals
Ozone (O ₃)	Formed in polluted areas; highest concentrations in smog	Strong oxidant to produce acids that attack most metals
Mineral acids (H ₂ SO ₄ , HCl, HF, HNO ₃)	Pickling industry, chemical industry, metals production, semiconductor industry	Most metals, glass, ceramics
Organic acids	Wood, packing material, animals, preservatives	Long-term effects on some metals

magnitude. Under these high-voltage gradients and high-conductivity conditions, most metals, including noble metals, will corrode actively through the electrolytic process, even without the presence of contaminants. The metal ions will diffuse through the surface electrolyte film toward the cathode, where reduction reactions lead to the formation of metal dendrites. The dendrites grow toward the anode and eventually short the circuits (Ref 40). This phenomenon is sometimes referred to as metallic treeing (Ref 41). Figure 4 shows the silver dendrite growth on the surface of an IC (Ref 42). Silver is not used in microelectronics for this reason.

Mechanisms of Corrosion in Microelectronics

In microelectronics, reliability hazards are most often caused by aqueous corrosion. Gaseous corrosion, which involves chemical reactions of metals at higher temperatures in the absence of moisture, is also possible, but it is generally less of a threat to reliability than aqueous corrosion. The mechanisms of corrosion in microelectronics and ancillary components include:

- Anodic, cathodic, and electrolytic reactions resulting in uniform corrosion

Table 4 Electrochemical series for reactions important in corrosion

Standard conditions: 25 °C (77 °F); 1 atm; H₂O; unit activities, metals present in their standard states

Electrode reaction	Standard potential, V (SHE)(a)

The form and rate of corrosion are influenced by the nature of the materials involved, the design, the packaging type, and the environmental conditions.

Uniform corrosion often occurs in the presence of a moisture film and ionic contaminants. If the electrical bias is sufficiently high, even noble metals will undergo electrolytic corrosion. The tendency of a metal to undergo oxidation is indicated by the electromotive force (emf) series, which is an orderly list of the standard reduction potentials of pure metals in equilibrium with 1 M aqueous solution of their own ions at 25 °C (77 °F). Table 4 gives the standard reduction potentials for some of the metals (and reactions involving oxygen and hydrogen) relevant to corrosion in microelectronics. A more extensive list can be found in *Corrosion:*

 **LIVE GRAPH**
Click here to view

**Fig. 5** Aluminum corrosion rates in acidic and alkaline environments at various temperatures and flow rates. Source: Ref 46

Materials, Volume 13B of *ASM Handbook*, 2005. The more negative the potential, the greater the tendency for the metal to undergo oxidation (corrosion). Aluminum is a reactive metal and is located at the lower end of the emf series. Reactive ion etching of aluminum metallization in plasma containing chlorine-base gases such as Cl₂, CCl₄, CHCl₃, and BCl₃ can result in rapid corrosion in the presence of moisture (Ref 24, 45). Other ionic contaminants may induce either an acidic or alkaline condition to the moisture film, causing accelerated corrosion of aluminum. Figure 5 shows that the corrosion rate of aluminum increases drastically outside the pH range of 4.5 to 7 (Ref 46). The potential-pH diagram at 25 °C (77 °F) for aluminum (Fig. 6) also indicates that active corrosion occurs outside the pH range of 4 to 8

(Ref 47). The presence of ionic contaminants such as Na^+ and K^+ can increase the conductivity of the electrolyte and shift the pH of the moisture film to the threshold value of 8 and above. The amount of sodium ions required is calculated to be $1.15 \times 10^{-5} \mu\text{g}$ for a hermetically sealed package with an internal volume of 0.1 cm^3 containing 5000 ppm_v of water vapor, of which 1% condenses on the chip (Ref 23).

Anodic Corrosion. The corrosion process, as in any other electrochemical system, consists of two half-cell reactions: anodic reaction and cathodic reaction. For example, the anodic reaction is simply the oxidation of aluminum:

This oxidation process occurs at the metal/oxide interface and involves diffusion of both Al^{3+} and O^{2-} or OH^- .

There are several possibilities for the cathodic reactions, depending on the pH of the electrolyte. Hydrogen evolution occurs in acidic environments where $\text{pH} < 7$:

In neutral or alkaline environment where $\text{pH} \geq 7$, oxygen reduction takes place:

If oxygen is limited, direct reduction of water will be predominant:

The overall reaction in the acidic environment is obtained by combining Eq 1 and Eq 2:

Equations 1, 3, and 4 can be combined to give the overall reactions in neutral and alkaline environments, where oxygen reduction is predominant:

Where reduction of water is predominant:

Cathodic Corrosion. The corrosion of aluminum discussed previously is anodic oxidation and, in the absence of ionic contaminants or electrical bias, is sometimes referred to as anodic corrosion. When aluminum metallization is cathodically biased, cathodic reduction takes place in accordance with Eq 2, 3, and 4, depending on the pH of the moisture film. In both Eq 3 and 4, hydroxyl ions (OH^-) are produced, leading to an increase in pH. Another source of alkalinity is the ionic contaminants, such as alkali ions of Na^+ and K^+ , that hydrolyze in the presence of moisture and increase the pH. Aluminum is amphoteric; that is, when the pH of the electrolyte is above 8 (Fig. 6), aluminum oxide is no longer stable and will undergo active dissolution (Ref 44, 46, 47), resulting in opens at the cathodic line. This phenomenon is often

referred to as cathodic corrosion. The hydroxyl ions attack the aluminum hydroxide (Eq 5) at the metal/electrolyte interface, resulting in the formation of soluble aluminate ions and hydrogen gas. The reaction is:

where oxygen reduction is predominant. The reaction is:

where reduction of water is predominant.

Research on the corrosion of pure aluminum in NaOH solution, with the concentration ranging from 0.01 to 1 M, showed that the predominant cathodic reaction is the direct reduction of water rather than the reduction of oxygen. Hence, the hydroxyl attack on aluminum oxide during cathodic corrosion is by the mechanism in Eq 9, with the release of hydrogen gas (Ref 48). The activation energy for cathodic corrosion was reported to be similar to that for the dissolution of aluminum in NaOH solution (Ref 49).

Electrolytic Corrosion. Noble metals are generally more resistant to corrosion than aluminum. For example, gold has a standard potential of 1.5 V (Table 4) and will not undergo oxidation under normal circumstances. However, when the electrical bias is higher than 1.5 V, gold can still undergo electrolytic corrosion, leading to the formation of $\text{Au}(\text{OH})_3$ (Ref 33). In the presence of halide ions, complex ion formation lowers the standard reduction potentials of gold from 1.5 to 0.96 V (Table 5), causing active corrosion.

The anodic reaction is:

The cathodic reaction is:

Fig. 6 Potential-pH diagram for aluminum at 25 °C (77 °F). SHE, standard hydrogen electrode. Source: Ref 47

The overall reaction is spontaneous, with a release of free energy of 22 kJ/mol (Ref 43):

For copper, the following reactions are involved.

The anodic reaction is:

The cathodic reaction is:

The overall reaction is also spontaneous, with a release of free energy of 172 kJ/mol:

Both ionic contaminants, such as chloride and gaseous contaminants such as ammonia and hydrogen sulfide, can significantly decrease the reduction potentials of the copper and silver systems (Table 5) to values as low as -0.62 V for copper and -0.45 V for silver, causing accelerated corrosion even in the absence of an electrical bias. This enhanced reactivity is responsible for the tarnishing of copper and silver in humid environments containing NH_3 and H_2S gases (Ref 51).

Dendrite growth, or electrolytic migration, refers to the reduction of metal ions in the form of metal dendrites along the diffusion path between conductors. The process involves the following steps:

1. Electrolytic dissolution of the metal (usually noble metals such as gold, silver, copper)
2. Migration of metal ions from anode to cathode through the surface electrolyte film
3. Electrodeposition of metal ions at the cathode in the form of dendrites
4. Propagation of dendrites toward the anode
5. Shorting of the anode to cathode across the dielectric

Noble metal ions, such as gold and silver ions, have a greater tendency to be reduced in the presence of moisture (Table 4). The source of metal ions mainly comes from the oxidation reaction at the anode. Under the electrical field, the positively charged metal ions migrate

Table 5 Standard electrode potentials for some noble metal systems

$\text{Au}^{2+} + e^- = \text{Au}^+$	< 1.29	50
$\text{AuCl}_2^- + e^- = \text{Au} + 2\text{Cl}^-$	1.11	47
$\text{AuCl}_4^- + e^- = \text{Au} + 4\text{Cl}^-$	1.00	50
$\text{AuBr}_2^- + e^- = \text{Au} + 2\text{Br}^-$	0.96	50
$\text{AgCl(s)} + e^- = \text{Ag} + \text{Cl}^-$	0.22	47
$\text{Ag}_2\text{S} + 2\text{H}^+ + e^- = 2\text{Ag} + \text{H}_2\text{S(g)}$	-0.45	47
$\text{CuCl(s)} + e^- = \text{Cu} + \text{Cl}^-$	0.14	47
$[\text{Cu}(\text{NH}_3)_4]^{2+} + 2e^- = \text{Cu} + 4\text{NH}_3$	-0.05	47
$\text{CuS(s)} + 2\text{H}^+ + 2e^- = \text{Cu} + \text{H}_2\text{S(g)}$	-0.62	47

through the surface electrolyte film toward the cathode where they are deposited (Fig. 4). It is believed that this diffusion-controlled process enhances the stability and propagation of dendrites. The phenomenon is sometimes also referred to as metallic treeing (Ref 41). Gold, silver, copper, and tin are some of the common electronic materials susceptible to dendrite growth on devices such as ICs and circuit boards (Ref 33, 52–59). Moisture and contaminants are known to accelerate dendrite growth.

Galvanic corrosion arises due to the difference in the electrochemical potentials of dissimilar metals in electrical contact, resulting in the accelerated attack on the anode, the metal with a more negative potential. This is probably the greatest single source of all corrosion failures. Galvanic effects are also responsible, in most cases, for the initiation and propagation of pitting corrosion on noble metal electrodeposits and on aluminum and gold metallization. In microelectronic components and devices, it is almost mandatory to use many different metals, either in direct physical or electrical contact.

Metal structures such as molybdenum-gold metallization and the aluminum metallization/gold bond wire interfaces are typical examples. In the presence of moisture and contaminants, a galvanic cell will form. The metal with a more positive potential acts as the cathode, and the one with a less positive potential acts as the anode. The driving force of the galvanic corrosion is the potential difference between the two dissimilar metals. For the aluminum-and-gold galvanic couple at the interface of the aluminum metallization/gold bond wire, the galvanic cell potential under standard conditions can be calculated from the standard reduction potentials (Table 4):

$$\begin{aligned} E_{\text{cell}} &= E_{\text{cathode}} - E_{\text{anode}} = E_{\text{Au}} - E_{\text{Al}} \\ &= +1.50 \text{ V} - (-1.66 \text{ V}) = +3.16 \text{ V} \end{aligned}$$

This voltage is over twice the voltage in AA alkaline batteries. The anode will experience accelerated attack.

For the aluminum-copper galvanic couple in the aluminum-copper bonding pads (Ref 60),

the galvanic cell potential calculated from the standard reduction potentials is 2.00 V. For the molybdenum-gold couple in molybdenum-gold metallization, the cell potential is 1.70 V. It is noted that the emf series assumes a standard equilibrium condition, where the metal is in contact with a 1 M aqueous solution of its own ions. This metal ion concentration is too far from actual concentrations in the surface electrolyte film. A more widely used series is the one measured in natural seawater, such as is found in the article “Galvanic Series of Metals and Alloys in Seawater” in *Corrosion: Materials*, Volume 13B of *ASM Handbook*, 2005. The aluminum-gold couple in seawater exposures produces roughly 1.2 V, which is still a significant driving force for accelerated attack at the anode.

Microelectronic components and devices are rarely exposed to an immersion condition, and corrosion of the various metal structures is mainly atmospheric in nature. Therefore, the galvanic series for metals exposed to atmosphere (Table 6) seems to most closely match the

Table 6 Metals and alloys compatible in dissimilar-metal couples

Group number	Metallurgical category	Electromotive force (emf), V	Anodic index(a), V	Compatible couples(b)
1	Gold, solid and plated; gold-platinum alloys; wrought platinum	+0.15	0	
2	Rhodium plated on silver-plated copper	+0.05	0.10	
3	Silver, solid or plated; high-silver alloys	0	0.15	
4	Nickel, solid or plated; monel metal, high-nickel-copper alloys	−0.15	0.30	
5	Copper, solid or plated; low bronzes or bronzes; silver solder; German silvery high copper-nickel alloys; nickel-chromium alloys; austenitic corrosion-resistant steels	−0.20	0.35	
6	Commercial yellow bronzes and bronzes	−0.25	0.40	
7	High bronzes and bronzes; naval brass; Muntz metal	−0.30	0.45	
8	18% Cr type corrosion-resistant steels	−0.35	0.50	
9	Chromium plated; tin plated; 12% Cr type corrosion-resistant steels	−0.45	0.60	
10	Tin-plate; terneplate; tin-lead solder	−0.50	0.65	
11	Lead, solid or plated; high-lead alloys	−0.55	0.70	
12	Aluminum, wrought alloys of the 2000-series	−0.60	0.75	
13	Iron, wrought, gray or malleable; plain carbon and low-alloy-steels; armco iron	−0.70	0.85	
14	Aluminum, wrought alloys other than 2000-series aluminum, cast alloys of the silicon type	−0.75	0.90	
15	Aluminum, cast alloys other than silicon type; cadmium, plated and chromated	−0.80	0.95	
16	Hot-dip zinc plate; galvanized steel	−1.05	1.20	
17	Zinc, wrought; zinc-base die-casting alloys; zinc plated	−1.10	1.25	
18	Magnesium and magnesium-base alloys, cast or wrought	−1.60	1.75	

(a) Anodic index is the absolute value of the potential difference between the most noble (cathodic) metals listed and the metal or alloy in question. For example, the emf of gold (group 1) is +0.15 V, and the emf of wrought 2000-series aluminum alloys (group 12) is −0.60 V. Thus, the anodic index of wrought 2000-series aluminum alloys is 0.75 V. (b) “Compatible” means the potential difference of the metals in question, which are connected by lines, is not more than 0.25 V. An open circle indicates the most cathodic members of a series; a closed circle indicates an anodic member. Arrows indicate the anodic direction

exposure conditions encountered in microelectronics (Ref 61, 62). The greater the anodic index (the potential difference between the anode and cathode members of a couple), the higher the galvanic corrosion risk. The conductivity of the surface electrolyte film will affect the rate and distribution of galvanic attack. Moisture accumulation when the power is off and contamination from both ionic and gaseous sources will increase the surface conductivity and hence enhance galvanic corrosion.

Pitting is localized attack on the metal structure, resulting in holes or cavities. In microelectronics, it is sometimes referred to as pore corrosion. It is commonly associated with noble metal coatings such as gold and silver on copper and nickel. The ultrathin and often porous noble metal coatings can leave the substrate exposed to the surface electrolyte film. The galvanic cell potential between the noble coatings and the less-noble substrate will initiate and accelerate the attack on the anodic substrate. The large cathode-to-anode surface area ratio also increases the acceleration factor, leading to rapid pitting of the underlying substrate. Halide ions such as chlorides are known to cause breakdown of oxide films and lead to the initiation of pitting (Ref 47, 63). On aluminum, the aluminum oxide is cathodic to the metal substrate. Ionic contaminants such as chloride can cause localized acidification due to the hydrolysis of aluminum chloride:

In reaction Eq 17, hydrogen chloride is produced, and this lowers the pH and accelerates the corrosion of aluminum in reaction Eq 1. As more Al^{3+} ions accumulate at the anode, electrostatic attraction tends to cause more Cl^- to diffuse into the pit bottom. This will accelerate reactions, leading to more HCl formation, which, in turn, causes more dissolution of Al^{3+} ions in the pit. This cycle of $\text{Al}^{3+} \rightarrow \text{Cl}^- \rightarrow \text{HCl} \rightarrow \text{Al}^{3+}$ repeats itself, and the process is self-accelerating, or autocatalytic, in nature.

Pitting on aluminum can also be initiated by the presence of more-noble metal ions such as copper. Copper ions from corrosion products can be readily reduced on aluminum. The galvanic effect between copper and aluminum is sufficient to initiate pitting on aluminum. Intermetallics in aluminum alloys such as FeAl_3 and CuAl_2 are cathodic precipitates that can also initiate pitting due to the same galvanic principle. Figure 7 shows schematically the mechanism of pitting on aluminum and the common factors involved in the process.

Creep corrosion is a mass-transport process during which solid corrosion products migrate over a surface away from the source metal. It is a known failure mechanism in electrical contacts and connectors. For example, tarnish films formed on copper and silver in humid environments containing NH_3 or H_2S can creep over

adjoining gold surfaces, leading to increased contact resistance of the gold. The driving force for the gold/copper system is most likely associated with the local galvanic cell between the dissimilar metals. For components with noble metal preplated leadframes, creep corrosion is considered to be a potential reliability hazard for long-term field applications. Field failure due to creep corrosion in telecommunication electronics is reported in the literature. The source, process, and possible products of creep corrosion on IC packages are discussed in Ref 2.

Fretting is a deterioration at the interface between contacting surfaces as the result of corrosion and slight oscillatory slip between the two surfaces. Associated components such as connectors, switches, and relays must maintain good conductive contact surfaces for thousands or millions of operation cycles. The effect of

fretting can seriously affect the contact resistance (Ref 64–66). Even noble metals are susceptible to fretting (Ref 67).

Stress Corrosion Cracking (SCC) is a cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. It has been known for almost a century that copper and its alloys are susceptible to SCC in humid atmospheres containing ammonium compounds (Ref 68). Other environments that can cause cracking of copper and its alloys include moist SO_2 , acetates, citrates, formates, tartrates, nitrites, and NaOH solutions. Aluminum and its alloys are susceptible to cracking in moist air and halide solutions. Precipitates along the grain boundaries in some aluminum alloys can result in intergranular corrosion. A quantitative model describing SCC of wire microjoints in microelectronics is given in Ref 69.

Fig. 7 Electrochemical mechanism of pitting on aluminum. Source: Ref 47

Table 7 Designing for corrosion-resistant finishes

Problem	Solution	Example
Dissimilar metals	Select metals from appropriate table of permissible couples (Table 6). Plate with compatible metal to reduce potential difference. Keep affected area of less-noble metal as large as possible.	Use nickel or rhodium, not brass or bronze, next to silver. Tinplate aluminum and bronze used together. Stainless steel hardware in sheet aluminum may be satisfactory because of large area of aluminum (but not the reverse).
Contact	Apply corrosion inhibitors. Interpose inert barrier or gaskets to prevent contact (extend 6.4 mm, or 1/4 in., beyond joint). Paint both metals (or cathode, at least) with alkali-resistant organic coating.	Vapor-phase corrosion inhibitors Vinyl tape, rubber gasket, dielectric washer MIL-P-52192 or MIL-P-15930
Electrolyte	Avoid designs where moisture can be trapped.	Use sealant bead on crimped, spot-welded, and threaded joints.
General	Use desiccant. Seal joint with organic insulation. Seal metal faces against contact with electrolyte. Where possible, avoid use of magnesium.	Useful only in hermetically sealed compartment MIL-S-7124 Primer, paint, or sealant Protection of magnesium requires very special attention.

Source: Adapted from Ref 62

Hydrogen embrittlement, or hydrogen-induced cracking, refers to the severe loss of ductility caused by the presence of hydrogen in the metal. In a corrosion process, both the reduction of hydrogen ions and the reduction of water will generate hydrogen atoms on the surface of the cathode. Processes such as electrocleaning, pickling, and plating can also produce hydrogen atoms. Absorbed hydrogen atoms can diffuse into the metal and cause the embrittlement.

Whisker growth refers to the filamentary growth on metallic materials that can cause short circuits. It is not a corrosion process but a mechanism of stress relief. The whiskers are not considered to be true corrosion products. Metal whiskers can grow even in hermetically sealed packages during storage. Common materials susceptible to whisker growth include electroplated tin, zinc, cadmium, copper, and silver. Failures caused by whisker growth in missile and aircraft radar systems are reported (Ref 70, 71). The process is retarded under low-humidity and low-temperature conditions.

Corrosion Control and Prevention

Control and prevention measures are naturally centered on the factors of materials selection, design, package type, and environmental conditions.

It is possible to minimize the corrosion effect by selection of compatible materials based on the design requirements. For avoiding galvanic corrosion, Table 6 provides guidelines on the compatibility of different metals. Table 7 provides guidelines on designing for corrosion-resistant finishes. Many metals used in microelectronic components and devices require protection from general atmospheric exposure (Table 8). The package type will play a vital role in preventing or reducing moisture ingress. Without the presence of an electrolyte, the corrosion process cannot take place.

Hermetic packages made of ceramics, glass, and metals are more resistant to moisture ingress than any plastic or polymeric packages by several orders of magnitude. The water molecules are small in size (with a diameter of 0.34 nm) and can diffuse through very small openings such as pores and cracks commonly found in plastic and polymeric materials. Figure 8 illustrates the time scale for moisture penetration for some common packaging materials. The following are essential and effective measures for minimizing the moisture retention in hermetic packages and/or moisture ingress in plastic packages:

- Proper selection and design of packaging materials
- Baking
- Dry sealing ambient
- Low leak rate for hermetic packages
- Low moisture permeation for plastic packages
- Wafer coating with good adhesion to the die surface

Moisture initiates and ionic contaminants assist and accelerate the electrochemical processes. Strict control of the sources of ionic contamination is essential (Fig. 2) in keeping the corrosion risks to the minimum. This includes processing equipment and materials (such as furnaces, etchants, and cleaning chemicals), packaging materials, fabrication environment, and human contact during assembly and handling. In addition to ionic contaminants, corrosive gases and vapors such as H_2S , SO_x , and NH_3 also require special attention, particularly the organic vapors from polymeric materials used in packaging (Table 9).

Corrosion inhibitors have been widely used in other industries to control corrosion processes. For multimetal systems, as encountered in microelectronic components and devices, effective inhibition of corrosion requires the inhibitor to simultaneously retard the corrosion of different metals, such as aluminum, copper, and tin. Inhibitors can be added to the polymeric encapsulant, typically epoxy resin, to retard the transport of ionic contaminants through the

package as well as to prevent the formation of corrosive electrolytes in the presence of moisture. Recent advances in corrosion-inhibitor formulation have resulted in an increased use of vapor-phase corrosion inhibitors in microelectronic control systems in the military and aerospace industries. The inhibitors are produced in a variety of formats, such as emitting devices, tablets, powder packets, stretch films, paper, and electronic spray. Within an enclosure, as is most often the case with microelectronic components and devices, the vapor-phase corrosion inhibitor can be an effective means of reducing the corrosion risks associated with moisture and contaminants during storage, shipping, and operation (Ref 73).

Corrosion Tests

The rate and forms of corrosion are affected by variables in both the materials and the environments. Hence, both materials tests and environmental tests are performed on microelectronic packages to detect flaws or defects that may lead to device failures during fabrication or field operation. Various electrochemical techniques based on direct current (dc) and alternating current (ac) are discussed in

Corrosion: Fundamentals, Testing, and Protection, Volume 13A of *ASM Handbook*, 2003. Direct current electrochemical techniques, such as potential and polarization measurements, are used to determine porosity in gold plating on copper-nickel substrates. These techniques also provide rapid and effective methods for the evaluation and selection of processing liquids, such as the etchants and detergents used in fabrication. Electrochemical impedance spectroscopy (EIS) is a proven powerful, nondestructive technique for the evaluation of polymer coatings. In encapsulated triple-track test structures, for example, EIS can be used to monitor the degradation of plastic packaging material and to determine the moisture pickup. The corrosion resistance and/or the effect of moisture ingress on the metal lines can also be monitored with EIS. Electrochemical techniques (ac and dc) have the advantages of high sensitivity and fast response, with typical test duration of less than 1 h. This is in sharp contrast with the various "accelerated" salt fog and environmental (temperature, humidity, and bias, or THB) tests that usually require 1000 h or more (Ref 74, 75). Microelectronic components and devices intended for exposure to corrosive environments are often subjected to environmental tests such as salt fog tests. These tests are similar to the original salt fog test proposed in 1914 and later standardized by ASTM International (Ref 76). Experience has shown that there is little correlation between the salt fog test results and the actual service life of electronic components, because the salt fog tests do not reproduce the actual service condition. Nevertheless, the tests are still widely used today, primarily as an arbitrary performance test for closely related materials. In microelectronics, the most commonly used accelerated tests are THB tests at 85% RH and 85 °C (185 °F), pressure-cooker tests at 100% RH and temperature above 100 °C (212 °F), and the highly accelerated stress test at RH below 100% and temperature up to 150 °C (300 °F).

The service life can be predicted based on the measured mean time to failure (MTTF) under accelerated test conditions:

$$\text{MTTF}_{\text{field}} = \text{AF} \times \text{MTTF}_{\text{test}} \quad (\text{Eq 18})$$

where $\text{MTTF}_{\text{field}}$ and $\text{MTTF}_{\text{test}}$ are the mean time to fail under field and test conditions, and AF is the acceleration factor. The AF can be expressed as:

$$\text{AF} = e^{\frac{E_a}{k_B} \left(\frac{1}{T_{\text{field}}} - \frac{1}{T_{\text{test}}} \right)} \quad (\text{Eq 19})$$

where E_a is activation energy, k_B is Boltzman's constant, and T is temperature in Kelvin.

Studies have shown that accelerated-temperature stress testing cannot be used to extrapolate to lower-temperature use conditions (Ref 77, 78), because the failure mechanisms introduced at the higher stress levels are not representative of actual use conditions. A more popular expression for the AF includes the

humidity and temperature:

$$\text{AF} = \left(\frac{\text{RH}_1}{\text{RH}_2} \right)^n e^{\frac{E_a}{k_B} \left(\frac{1}{T_1} - \frac{1}{T_2} \right)} \quad (\text{Eq 20})$$

where RH_1 , RH_2 , T_1 , and T_2 are relative humidity and temperature, respectively, at two stress conditions.

Because corrosion is also influenced by contaminants, the commonly used THB tests have a problem with the omission of contaminants that may become a controlling factor in a failure mechanism. Without contaminants in the stressing environment, the THB testing is essentially a measure of the cleanliness of the part prior to testing. In order to improve the correlation of the environmental test results with actual field performance, controlled contamination can be introduced into the test environment.

Corrosion in Semiconductor Wafer Fabrication

Mercy Thomas, Gary Hanvy, and Khuzema Sulemanji, Texas Instruments

THE MICROELECTRONICS INDUSTRY is one of the fastest growing industries in the United States due to the constant development and application of new products in data storage, communication, and computing. Constantly shrinking device dimensions enable integrated circuits to become more powerful while the cost of manufacturing continues to drop. At the heart of the industry is the ability at the wafer-fabrication plant to implement the complicated processes needed to deposit, pattern, and etch circuits in semiconductor materials.

One key to the fabrication of integrated circuits is the method of removing selected areas of a conductive-deposited aluminum-copper film. The remaining metal lines are interconnects that join the active components in the integrated circuit. The copper addition to the aluminum increases the reliability of interconnects by preventing the failure mode of electromigration. Electromigration is the unwanted movement of metal atoms in the conductor influenced by current density and temperature that can result in short circuits or open circuits. Metal plasma etch is one of these techniques in which metal lines (or leads) are formed by removing surrounding metal in a chemically reactive low-pressure plasma.

Corrosion is one of the major problems associated with the metal plasma etch process. Dry etching in a chlorine-containing plasma is a potentially important technique for patterning aluminum alloy lines for very large scale integration (VLSI) circuits. However, aluminum alloy lines formed by dry etching are prone to corrode upon atmospheric exposure. The inclusion of copper in the alloy may result in accelerated corrosion of aluminum in the presence of chlorine and moisture during the plasma etching. This is not only an in-process corrosion problem, but also a reliability issue for the metallization of the circuits. Corrosion is typically detected by either manual or more commonly by automated microscopic inspections. The experience of one wafer-fabrication facility to combat the problem is outlined in this article.

Corrosion During Fabrication

In wafer fabrication, much effort has been made to anticipate and avoid corrosion because failure to do so can result in unexpected and catastrophic failure of semiconductor parts either during quality-assurance testing during production or in the field. The impact of corrosion is severe on processing yields and product quality.

Metallization and Chlorine-Induced Corrosion. Corrosion most commonly appears within the metallization process levels between metal deposition and the formation of the oxide layer following metal lead etch and solvent cleanup. A typical corrosion defect is shown in Fig. 1. The mechanism of corrosion is:

With an atmosphere of 30 to 60% relative humidity (RH),

The source of the chlorine could be the sidewall polymer where it can be trapped and then can attack the aluminum leads if they are not put in the solvent stripper. Trapped chlorine in thin-etch residue causes severe pitting corrosion. The etch residue can consist of organic, inorganic (from etch species of Cl and F), metal-organic, and metalinorganic species. Combinations of these make them more difficult to remove. Aluminum oxychloride (AlClO) is formed due to time delay between etch and wet strip. AlClO is soluble in water and stripper. Chloride corrosion at the plasma step is not seen until the wet strip is complete; hence passivating the sidewall is critical to prevent latent corrosion due to residual halides from etch residues.

Fig. 1 Corrosion of the aluminum alloy metal lines on a wafer seen (a) in plan view with a light microscope and (b) in profile with a scanning electron microscope (SEM)

The corrosion-prevention effort timeline (Fig. 2) summarizes the activities at the fabrication plant to identify corrosion sources and implement the corrective actions. Each

stage emphasized specific areas of the wafer-fabrication facility.

Fabrication Stages. The physical locations of stations in a typical wafer-fabrication pro-

cessing unit are given in Fig. 3. The occurrence and reasons for corrosion are summarized.

Prior to Metal Etch. Corrosion is due to supercarrier or boat contamination (Fig. 4).

Metal Lead Etch in Batch Etchers. Batch etchers (Fig. 5) are identified as 8330 on the fabrication unit layout (Fig. 3). Corrosion is due to:

- Presence of photoresist remaining after the metal lead etch process
- Lack of a fluoride substitution process in the metal-etch recipe
- Lack of a organic polymer passivation in the metal-etch recipe

Metal Lead Etch Stage in Single-Wafer Etchers. Single-wafer etchers are identified as 9600 in the fabrication unit layout (Fig. 3). Corrosion is due to:

- Improper control of atmospheric passivation module (APM) process
- Decoupled source quartz (DSQ) photoresist-removal process
- Polymer corrosion due to mid-chamber wear
- Environmental effects due to proximity of etchers to each other or due to foreline maintenance

Solvent Cleanup after Metal Etch. Corrosion is due to:

- Solvent hood setup (dispersion plates) and filtration system
- Failure to maintain product time limits between metal lead etch and solvent cleanup
- Failure to use nitrogen cabinets for storage between metal lead etch and solvent cleanup
- High RH levels in the fabrication area
- Failure to strip all polymer from the wafer in the solvent cleanup process

Environmental effects that could occur at various production stages include:

- Opening of the foreline to chlorine or etch polymer contamination
- Metal-etch tool cleanup affecting other nearby tools
- Poor airflow

Corrosion at these stages is examined in more detail in the sections that follow.

Corrosion Prior to the Metal Lead Etch Process. The source of this defect is identified by observing the pattern of the corrosion on the wafers. Corrosion occurred only around the extreme edge of the wafer. Little or none was observed around the wafer flat or at the wafer edge opposite the flat. When stored in a supercarrier, the wafer flat is always up in the boat and the wafer round (edge opposite the flat) is always down. The areas clear of corrosion are never in contact with the interior surface of the boat slots. Further testing with controlled conditions duplicated the corrosion defect, and the source was determined to be from the supercarrier boats used when transporting wafers from one processing stage to another.

Other wafer-fabrication units within the company were polled, and the consensus was that they did not have the same issue. The units without the incoming corrosion problems managed their supercarrier boats in a manner that made sure boats were switched either before or just after metal deposition.

In order to implement a boat switch at metal deposition, more boats would have to be purchased. To avoid this additional cost, a novel deionized water boat wash procedure was implemented whereby supercarrier boats were collected at the metal-deposition process and washed. Now wafers completing the metal-deposition process are placed into a freshly cleaned boat.

Corrosion Issues Related to Batch Metal-Etch Systems. Batch metal-etch systems, such as the 8330, can be considered a source of corrosion since the photoresist cannot easily be immediately stripped following etch as can be done in single-wafer metal-etch systems. Figure 6 shows that batch systems are more likely to produce parts with corrosion defects than are the three single-wafer etchers.

Corrosion in the batch metal-etch system stems from the presence of aluminum chloride residue. The residue is produced from photoresist and other foreign materials present. The

aluminum lead sidewall will trap chloride. The more porous the sidewall, the heavier the corrosion.

Corrosion-prevention measures in the batch systems include:

- Ensure a residue-free etch as much as possible.
- Perform a fluoride-substitution treatment by converting the chloride residue into fluoride that is inert to moisture. This step is called the “fluorine/chlorine exchange step.” The step consists of washing the parts with 100 standard cubic centimeters per minute (sccm) CF_4 for 2 min.
- Perform an organic polymer passivation step using trifluoromethane (CHF_3) to form a stripable protective coating. This step is called the “anticorrosion step.” The step consists of coating the parts with 60 sccm CHF_3 for 6 min.
- Strip the photoresist as soon as possible after etch. This requires tight control of sit times between etch and cleanup.

Of these items, three are key: the fluoride substitution, the organic polymer passivation, and the control sit time between etch and cleanup (Ref 1).

Corrosion Issues Related to Single-Wafer Metal-Etch Systems. Single-wafer systems, such as the 9600, have an advantage over batch systems in the prevention of corrosion by the sequence of process modules. The main etch chamber is followed by the DSQ photoresist strip chamber, and then by the APM rinse. Even so, the most common corrosion causes can be grouped under the two categories of APM and DSQ setup and maintenance. When either fails, the typical concentration of the corrosion is dense across the wafers as in the wafer map (Fig. 7).

Atmospheric passivation module processing has critical parameters that need to be controlled and monitored closely: water temperature and pressure, wafer chuck spin speed, exhaust,

nitrogen nozzle pressure and positioning, and nitrogen curtain flow. Of these, water temperature has the largest impact on corrosion based on test results. The defects for wafers processed at various APM water temperature set points and spun at 500 and 1000 rpm are shown in Fig. 8. Corrosion defects reached a first maximum at the 55 °C (130 °F) set point at 1000 rpm and the 60 °C (140 °F) set point at 500 rpm. Spin speed did not have much impact until the 80 °C (176 °F) set point was reached. Choosing the correct water-temperature set point and preventing drift of all the critical APM parameters through proper adjustment and maintenance of the equipment is key to controlling APM process corrosion.

Decoupled source quartz photoresist removal process relies on these critical parameters that must be monitored: photoresist strip rate, photoresist strip uniformity, paddle temperature, and water vapor concentration. If the DSQ setup is optimum and is operating correctly, the water vapor introduced in the initial step is the key parameter from the list. It neutralizes or removes the residual chloride surrounding the etched metal leads. Next in importance is the photoresist strip rate and uniformity. It is essential that the photoresist is removed completely, leaving no residual on the wafer for electronic as well as corrosion reasons. Proper monitoring and maintenance of the DSQ chamber is needed to ensure corrosion is kept to a minimum (Ref 2, 3).

Mid-chamber Wear. Wafer corrosion on the single-wafer system can occur due to mid-chamber wear in the following manner. As a result of process etch gases eroding the anodized aluminum walls of the plenum, a corrosion by-product is formed. This by-product will then be deposited on the wafer surface, making the photoresist very hard to remove in the DSQ and even in the following solvent cleanup steps. The residual photoresist will result in metal lead corrosion on the wafer.

To prevent this, the machine manufacturer developed an upgrade whereby they lined the gas plenum with ceramic. This extends the top plate

Fig. 5 A batch metal etcher, model 8330, installed in the fabrication unit

Fig. 6 Data showing batch etchers are more prone to corrosion than single-wafer etchers

Fig. 7 Wafer map of typical corrosion defects. Black spots are random corrosion. Gray (or green) spots in circle are clustered corrosion.

over the anodized aluminum middle chamber, fully enclosing the gas plenum with ceramic (Fig. 9). It prevents exposure of the chamber walls to process gases and extends the mid-chamber life indefinitely, as well as helping to prevent corrosion to the product (Ref 4).

Moisture from the fabrication-room environment is a corrosion concern. When wafers are sitting in the clean room after metal lead etch, they are at a high risk to be corroded by exposure to the atmosphere. To prevent moisture attacking the metal leads, wafers are stored in nitrogen cabinets, where nitrogen is continuously circulated. Nitrogen serves as a corrosion prevention, but does not guarantee the absence of corrosion. Time limits are set for the sit time, the time between metal lead etch and solvent cleanup, to reduce the chance of corrosion. The sit-time limit is approximately 1 to 2 h after metal lead etch. Wafers are stored in a nitrogen environment and can be held up to the sit time limit before processing in solvent cleanup. Chloride residue from the photoresist attacks metal leads and needs to be removed before the waiting period.

The oven-bake process is introduced to dry out residual chloride from photoresist. Wafers are put in ovens as soon as they come from the batch metal etchers. Ovens operate at 150 to 250 °C (300 to 480 °F), which dries out the chlorine before the ash and solvent strip. However, the oven-baking step hardens the photo-

resist, and it is then more difficult to remove. The ash and solvent-strip removal parameters must be optimized.

Solvent Cleanup after Metal Etch. The composition, flow characteristics, and maintenance of the solvent will impact the possibility of degradation to the wafers.

Solvent Deionize Water Content. Solvents are used at the stripping step. The cleaning effectiveness of many of solvents is sensitive to the water content of the solvent. A low deionized water content would not provide an efficient cleaning, but a high deionized water content would cause corrosion.

Dispersion Plates. A dynamic flow in the solvent tank is essential to provide a good mechanical motion between solvent and wafers. Dispersion plates should be installed at the bottom of solvent tanks. These are stainless steel plates with small holes (Fig. 10) that restrict overly concentrated flow in the wafer zone and help to deliver an even flow to the wafers. A good circulation of solvent takes the polymer and photoresist from the wafers to the bottom of the tank where they are trapped by the filters. If wafers are processed in a tank of dirty solvent, corrosion appears as in Fig. 11. A good filtration system will keep the solvent clean.

Dual-Filtration for Solvent Bench. As line widths of conductors on the wafers decrease, defects that were previously not a concern

become more important. Flow rate is a key parameter to monitor in a solvent-bath filter system. A single-filter system may not be sufficient on a dirty solvent-strip process. For an application where the photoresist remains after the etch, a dual-filter system consisting of a coarse polyguard filter plus a fine microguard filter works well filtering solvent containing both large and small photoresist particles. Improperly sized filters can leave a residue in the solvent that results in wafer corrosion. Also, solvent-bath change and filter change at rigid frequencies are required due to loading effects. The frequency of change can be time based or based on the number of wafers processed.

Fluorine corrosion occurs when an excessive amount of water remains on the wafer surface (Fig. 12). Heater failure, poor nitrogen flow, or a bad door seal of a spin-rinse dryer can cause the wafers not to dry completely after a rinse cycle. Corrosion occurs if wafers are not dried immediately to minimize the wafer contact to moisture.

Material Segregation. Metal leads with chloride residue should be processed separately from other material in solvent cleanup to avoid cross-contamination. The residual chloride may corrode wafers without photoresist. For instance, wafers from a batch-metal etcher and wafers from a single-wafer etcher must be run independently in the solvent because residual chloride is present on batch wafers, but not on single wafers. Chloride residue attacks the single wafers and results in corrosion damage.

Corrosion Due to Environmental Effects

Environmental factors within a wafer-fabrication unit (fab), such as acid vapors released into the air, are potential sources for contamination. A study focusing on the release of chlorine vapors into the fab environment during a tool maintenance activity and its effects on wafer integrity was conducted.

This study considered a ballroom-type wafer fab using an 8330 batch etcher (Fig. 5) as the test tool that was the source of the chlorine vapor. The 8330 etcher requires preventative maintenance (PM) to remove polymer or etch residue buildup within the process chamber.

At PM intervals, the process chamber is vented to the fab room where low concentrations of chlorine within the polymer are released. The chlorine interacts with the water vapor in the air and forms low-grade hydrochloric acid (HCl) vapors.

The first phase of the study involved placing preinspected wafers with 2.0% aluminum copper deposition (witness wafers) in locations near the 8330 metal etcher before opening the process chamber to atmosphere. The locations are identified around the test tool as A, B, and C in the Fig. 3.

The chamber was then opened and a normal PM was performed. At the conclusion of the PM, the wafers were inspected for visual defects (Table 1). The wafers were then processed on a TCP 9600 metal etcher using a standard recipe to

determine if the postetch process enhances the effects of corrosion. The data indicate that wafers with metal deposition, which are exposed to HCl vapors or byproducts, have the potential to corrode. This is

confirmed by the incomplete etch defects viewed after metal-etch processing. Of the three sets of wafers placed around the metal etcher, only the wafers placed in a location A showed metal corrosion. This indicates that there are other fab conditions that affect corrosion such as residence time and air-flow dynamics.

The second phase of the study focused on the allowable residence time of HCl vapors and its impact on wafer integrity. A repeat of the first phase of the study was performed using only location A (Fig. 3). Witness wafers were set out at the initial opening of the process chamber and at 10 to 30 min intervals thereafter. A visual inspection of each set of wafers was then made and is shown in relation to the PM steps (Fig. 13).

Figure 13 shows that there is some amount of residence time before the corrosion can be seen. No corrosion was seen during the initial inspection, although the wafer had been exposed to a burst of vapors as the chamber was opened. It was approximately 40 min later before the corrosion could be seen on the original witness wafer. The wafers that were switched out at specific intervals continued to show corrosion as the PM continued. Corrosion did not stop until the chamber cleaning maintenance was complete.

The results of both the first and second phases of this case study raised the question of the importance of air-flow dynamics. A third phase of this case study was initiated focusing on air-flow dynamics in and around the original test tool (Fig. 14). A fogger-type device was used to view the flow dynamics at different locations throughout this area.

The results of the test indicated that good vertical laminar flow existed in most areas. Location points A and B (Fig. 14), however, showed an air-flow drift toward location C (which is location A test point used in the first phase (Fig. 3)). The air-flow dynamics of the room guided the HCl vapor toward this location,

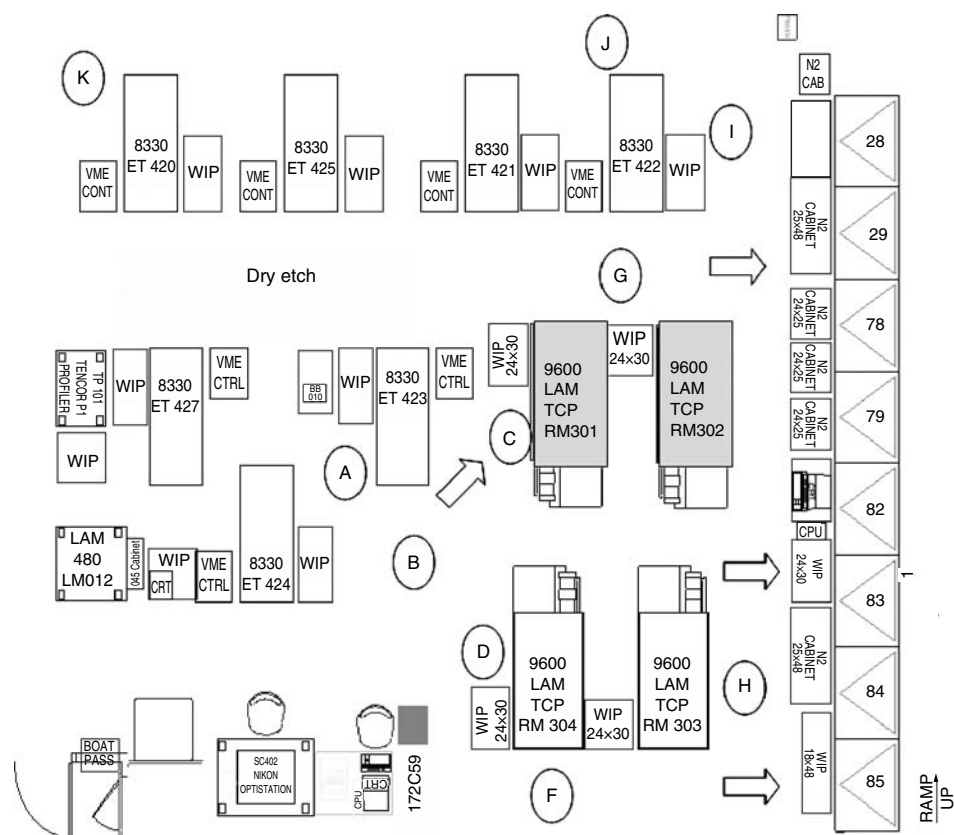

Fig. 14 Air-flow dynamics in the fabrication unit. Arrows indicate horizontal flow. Circled letters are test locations. Shaded objects are the single-batch etchers.

and only wafers in this vicinity were affected. The area, in general, was observed, and it was noticed that variation in floor tile perforation and the bulkiness of the tools contributed to this air-flow drift.

This case study showed that factors outside the normal processing of wafers (example foreline maintenance and other PM) or tool-specific problems can contribute to metal-line corrosion. The best solution is to remove the possibility of

HCl exposure altogether. Unfortunately, that is not always possible. Measures should be taken to mitigate the amount and frequency of HCl exposure. In certain scenarios, consideration should be given to stop wafer processing and remove the wafers from the area until normal fab unit conditions return.

ACKNOWLEDGMENT

Special thanks to Martha Adams, Plasma PE senior technician who helped set up and run some of the case study evaluations.

Corrosion in the Assembly of Semiconductor Integrated Circuits

A.C. Tan, Micron Semiconductor Asia

METALS USED IN SEMICONDUCTOR INTEGRATED CIRCUITS (SICs) serve several functions. Within the chip, metal lines provide local interconnection to join a collection of circuit elements globally to various areas of the chips, and they also provide input/output signals. Aluminum is currently the most commonly used metal for integrated circuits (metallization and bonding pads), but copper is increasingly being used for the high-end (ultralarge-scale integrated circuitry) products because it exhibits a lower electrical resistivity and better electromigration resistance than that of aluminum. The chip is connected to the outside world by a wire bonding (or other forms of interconnects) and a leadframe (which is the metallic portion of an assembled IC package and is used to complete the electrical connection path from the die to defined circuit elements of a printed board assembly), or a patterned laminate (also known as a plastic interposer, commonly with plated copper traces). The terminations of the leadframes are plated with a solderable metal or alloy, such as tin and tin-lead alloys. These metals are susceptible to corrosion.

In a typical IC component, corrosion may be observed at the chip level and at the termination (also known as leads) area, as illustrated in Fig. 1. In this figure, a thin-small-outline package (TSOP) is shown along with the various areas where corrosion can occur. For chip scale package (CSP) type of packages with solder

balls as interconnects between the package and a printed circuit board, similar corrosion sites may occur, except that the entry path may be different. Generally, it is rare to see a solder ball corroded. Chip corrosion refers to either the corrosion at the bond pad, or corrosion at the metallization, with thickness usually around 0.5 to 1 μm . Device terminations refer to the leadframe, commonly Alloy 42 (ASTM F 30, 42% Ni, 58% Fe) or copper, usually coated with either solder or tin, with typical thickness ranging from about 6 to 12 μm . In some components, the copper leadframes are coated with a solderable palladium or gold flash (typical thickness, <0.125 μm).

Chip corrosion could cause a reliability (functional) failure in an electronic device. Corrosion of the device terminations (known as macrointerconnects) results in lead (termination) tarnishing, which is, in a mild form, an aesthetic issue, and in the worst form, a contact resistance problem or a solderability problem at the board assembly. Due to the corrosion, the metals are said to be corroded, oxidized, or tarnished (Ref 1–5). Generally, the macrointerconnects are more exposed to the ambient environments, while the chips are protected by the encapsulants (compounds for a plastic encapsulated device). However, the dimension of the macroconnects is generally in mils (1 mil = 25 μm), while the metallization of the chips is about 1 μm . Failure due to the corrosion of the macrointerconnects is not as catastrophic as corrosion at the chip. Generally, corrosion of the macrointerconnects may be “reworked,” while chip corrosion would mean that the chips are to be scrapped, not reworkable at all.

Factors Causing Corrosion

Corrosion of metals has been extensively studied with volumes of monographs and articles (Ref 2–4), and the key factors contributing to corrosion of electronic components are:

- Chemicals (salts containing halides, sulfides, acids, and alkalis)
- Temperature
- Air (polluted air)

- Moisture
- Contact between dissimilar metals in a wet condition
- Applied potential differences
- Stress

The most common factors are the combination of all of these factors, except the stress factor, which occurs less frequently.

Routes of Corrosion. Semiconductor components are subjected to a variety of exposures during the manufacturing of the components and when assembled on the board. Thus, corrosion may be routed differently. In general, two types are observed: corrosion driven by the application of an applied potential, and corrosion occurring under open circuit (static) conditions. The focus of this article is on the latter. For corrosion driven by an applied voltage, readers may refer to Ref 6 to 8.

Chemicals are found practically everywhere in typical device fabrication (known as front-end) and assembly (known as back-end) processes and can contaminate the device when care is not taken to minimize the exposure. It is known that air contains airborne particles (especially in a place with heavy industries or heavy vehicular flow). Airborne particles are, basically, a mixture of hydrocarbons, silica, magnesium oxide, sulfides, and iron oxides. The actual composition varies with different air environments and sources.

Wet processes involving solvents, plating baths, and fluxing agents are used in the IC assembly and chemicals are also used in making the packaging materials (known in the electronics industry as piece parts). Examples of the piece parts used in the assembly of SIC are leadframes, die-attach (adhesives), wire (about 1 mil in diameter), and molding compounds. Chemicals are used in the plating process and in the post-plating processes (e.g., burn-in, cleaning of the units after a burn-in process). The most corrosive chemicals used in the assembly are the plating chemicals (precleaning chemicals and plating chemicals) or fluxing. In the early days prior to the banning of ozone-depleting chemicals, a chlorinated solvent, 1,1,1-trichloroethane was a common solvent. If the solvent is dispensed at the vicinity of a furnace,

Fig. 1 Areas where corrosion can be observed in a typical IC component. 1, Bonding pad corrosion; 2, Inner lead corrosion; 3, Leadframe (external leads) corrosion due to environmental impact. The IC package shown here is a partial thin small outline package (TSOP) with molding compound removed showing the silicon die, bonding pad, and the external and inner leads. Source: Ref 1

decomposition of the 1,1,1-trichloroethane is expected, giving rise to a corrosive hydrochloric (HCl) gas, which could subsequently corrode the terminations if the components are stored in the vicinity.

The chemical ingredients used by the piece parts (materials for the packaging and assembly of silicon dies) are generally inert (noncorrosive); however, ionic impurities (due to the incoming materials and processing) may be present, and hence it is imperative that the level of the ionic impurities is controlled, usually to less than 10 ppm. One of the important ingredients used in the molding compounds is a releasing agent, carnauba wax, which is basically a mixture of long-chain hydrocarbons, ester, amides, and organic acids. Outgassing of these compounds occurs when the encapsulant is heated. This may cause tarnishing of the leads and an increase in contact resistance. Additionally, the outgassing of the wax materials is also detrimental to the wire bond integrity when the SIC is undergoing a high-temperature storage (HTS) test because some of the outgassing products are corrosive.

Process Flow of IC Packaging. The assembly of electronics parts follows a series of processes, as illustrated in Fig. 2, where some corrosive chemicals and elevated temperatures are involved. Corrosion (chip corrosion, tarnished terminations, and rusty discoloration with iron rust or rings of multiple color) has been observed since the beginning of semiconductor

device manufacturing. With a better understanding and lessons learned from operation in the field, its occurrence is more manageable now. Let us examine the assembly processes where corrosion may take place when process or material control is lacking. Generally, the ionic contents of the packaging materials are to be controlled, at about 10 ppm or lower. Each of the steps has potential area for corrosion if not properly controlled. Among the processing steps, the plating process is the most corrosive. Surface finishing (plating) is a process (an integral part of the assembly) using a series of corrosive chemicals for etching, plating, and neutralization. If residues are left on the package (plastic body and leadframes), the reliability of the device can be potentially affected.

In a burn-in process, packages are subjected to a long duration (hours) of heat treatment (for static condition, about 125 °C, or 255 °F, for a dynamic condition, between cold and hot). Tarnishing of the leads can be observed if no proper care is taken to manage the testing conditions. Solderability problems are likely to occur when the leads are severely tarnished.

Chip Corrosion

Chip corrosion (bond pads and metallization) has been extensively documented and cited in the literature (Ref 1, 6–10). Fluorine is commonly found on the bond pads due to the fluorine-containing etching chemicals not being completely removed. Hence, the patterned wafers are tightly packed so that moisture is kept away from the wafers. The bond pads, when exposed to the moist air, are susceptible to corrosion, as it is known via auger analysis that traces of fluorine are usually present. Corrosion products are the mixture of aluminum oxides and aluminum oxyfluoride salts. Bonding with these corroded pads would encounter “nonstick,” or weak adhesion wire bonding, hence creating a serious reliability problem where the aluminum pad and gold wire are separated. Piece parts used in the assembly, such as die-attach and molding compounds, may contribute to the corrosion if the impurities levels (particularly halides and salts) of the piece parts are not controlled.

Brominated resins are commonly used as a flame retardant in a compound formulation and provide a source of halide ion (e.g., bromide) to cause corrosion of the chips. Surface finishing processes, such as solder dipping or plating (tin or solder), are another source of corrosive chemicals. When left uncleaned, the chemicals may diffuse into the compound via crevices and result in poor adhesion between the compound and the leadframe.

Oxidation of Tin and Tin Lead Alloys (Solders)

Oxidation refers to a reaction whereby the metal is transformed to a metal oxide upon

exposure to air and temperature. It is a corrosion reaction. For example, like most metals, tin or solder has a native oxide layer on the metal surface. Tin oxide (SnO or SnO_2 , or a mixture of the two oxidation states of tin) is a passivating film with thickness approximately a few angstroms. In the presence of wet conditions, temperature, and ionic species, further oxidation may occur, producing more tin oxides. The color of the oxides depends on the thickness. It ranges from tinge-blue or yellow, yellow, purplish blue, and black, and all of these are tarnishing (Ref 2, 5). Oxidation of solders is similarly dependent on the aging condition (O_2 -rich or N_2 -rich), ionic species, temperature, and moisture level (Ref 11, 12).

Generally, solders are also passivated with a layer of a mixture of tin and lead oxides. Tin is slightly more anodic than lead. The standard electrode potentials for tin and lead are -136 and -126 mV, respectively, thus tin oxide is preferentially formed. However, the composition of the oxides involves more than the electrode potentials; kinetics plays an important role as well (Ref 11, 12). Reflowed solders have two distinguishable phases, tin-rich and lead-rich. Electroplated solder (in various compositions) contains tin and lead and has a well-defined grain structure. The reflowed solder and electroplated solder contain mainly tin and lead, but they are different structurally. Hence, the nature of the oxides formed for the reflowed solder and electroplated solder would depend on the surface composition and the environment. When there is a limited supply of oxygen (e.g., in a N_2 purged oven), there is a competition between the surface composition and structure, as described in Ref 13 and 14. In a normal condition (air-filled burn-in oven), a mixture of the oxides is formed. The composition of the solder oxide depends on the surface composition and the environment.

Tin oxide is a passivating film, but, in the presence of air (O_2), corrosive chemicals (e.g., Cl^- ion), and moisture, the oxide is attacked, converting tin oxide to a stannous chloride (SnCl_2) salt. The SnCl_2 salt is a loosely bonded salt; in the presence of water (moist air) and carbon dioxide, it may be changed to a tin carbonate. The corrosion reactions make the surface tarnished or colored, depending on the extent of the oxidation. For long-term storage of IC units with a solder finishing, the solder oxides formed are a mixture of tin and lead oxides, and the salts, commonly lumped as “oxides.”

Mechanism of Tarnished Leads (Terminations)

Tarnish of leads has been observed in several forms:

- All leads are tarnished (various colors and shades).
- Tarnish occurs at the interface between compound and leadframe (usually rusty color).

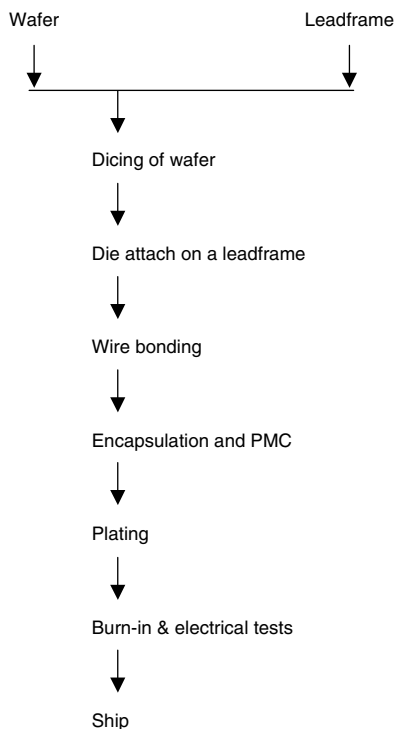

Fig. 2 Generic process flow of a semiconductor device. Key areas where corrosion could occur are shown. PMC refers to post mold cure, a process whereby the encapsulant (molding compound) is further cured.

- One or two pins are tarnished while the rest of the device leads are not tarnished.
- Leads are rusty with multiple color on the plastic body and leadframe.

The mechanisms are corrosion (aqueous and dry corrosion) and galvanic corrosion. The ingredients that trigger the corrosion are the usual factors: chemicals, moisture, and temperature. The place of occurrence could be found after plating and post-plating processes such as trim-form, burn-in, and solder reflow.

Tarnished Leads Caused by a Galvanic Corrosion. A classic example of a galvanic corrosion is the aluminum bond pad corrosion (Ref 1, 5–10) where the gold acts as the cathode, and aluminum acts as the anode. The corrosion leads to a continuity failure when the aluminum pad is depleted. The attributes of this chip corrosion are the ingress of moisture and ionic contaminants. Two major sources of ionic contaminants are observed: piece part (molding compounds and die attach) and the residues from the flux or plating chemicals. The ionic impurities of the die-attach and molding compounds of the early years (1970s and 1980s) were not properly controlled, and corrosion of the chips was commonly encountered. However, most current die-attach and compounds have the chloride level and other aggressive ions controlled at about 10 ppm. Similarly, if the HCl acid and other corrosive chemicals remain on the plastic body, the chemicals could ingress into the plastic compound and corrode the bond

pad. Eventually, a discontinuity problem can be observed. The aluminum bonding pad is eventually corroded, forming aluminum trihydrate ($\text{Al}(\text{OH})_3$) as a corrosion product. The rinsing and drying parts of the plating and soldering process need to be optimized such that the package, after plating or soldering, is optimally cleaned. Rinse effectiveness of the process may be measured by the use of a resistivity measurement (Ref 1). The industry has learned from the harms caused by the corrosive residues, and actions have been taken so that the history of corrosion is not repeated. With better management of the wet processes, leadframe design, and materials selection, bond pad corrosion is now rarely experienced.

Galvanic corrosion can also be observed in the assembly. One case is illustrated in Fig. 3, where only a few pins of the entire package are corroded (in this case, two pins of the entire package). In another similar case, an imprint of terminations was seen on a gold lid of a ceramic package as shown in Fig. 4. These two cases are the result of a mishandling arising from a wet process (see also the subsequent discussion on oxide wash and ink symbol rework).

The burn-in process, if not controlled properly, can result in severely tarnished leads. Tarnished leads found during this burn-in process are caused by factors such as temperature, bad door seal of the burn-in oven, humidity, plating chemical residues remaining on the terminations, and the cleanliness of the burn-in sockets. The outgassing of polymeric materials used in a burn-in board and encapsulants (e.g., epoxy molding compounds used in many IC devices) could also contribute to the tarnishing of the device leads. Traditionally, a subsequent

“oxide wash” is the usual remedy to salvage the affected lot. Typically in an oxide wash process, an acid or alkaline solution is used to clean off the oxides. By mistake or improper design of a loading and unloading tool, a galvanic couple is created. A stainless steel jig or handler is commonly used in the industry because it is robust and can be easily used in a wet process. However, the package terminations (pins) coated with solder/tin may be in contact with a stainless steel jig during the wet process. Corrosion of the solder (tin) takes place when there is a contact, and in the presence of a wet condition (e.g., an acidified solution). Figure 5 schematically explains the galvanic action taking place. The etched tin or solder surface, when subjected to drying after the wet process, is further oxidized, resulting in a darker appearance as compared with the noncorroded pins (refer to Fig. 3). This mechanism explains the appearance of one or two pins being tarnished, while the remaining pins are unchanged. Galvanic corrosion does not take place when there is no contact.

The imprint of leads on a gold lid of a ceramic package (a high-reliability product), as illustrated in Fig. 4, shows another example of galvanic corrosion due to dissimilar electrodes in contact. In the presence of an electrolyte and temperature, galvanic corrosion occurs. In the days of the ink symbolization process, mistakes could be made (e.g., wrong symbol or poor symbol). Traditionally, a rework of the cured ink symbol was done by soaking the gold lid package in a sodium hydroxide solution at an elevated temperature. If the cleaning was properly carried out, the cured ink would be removed and the package reused. However, if the ceramic

Fig. 3 Diagram showing a partial thin-small-outline package with tarnished leads caused by galvanic corrosion. Notice that two pins, out of ten, are tarnished. In some cases, only one pin is tarnished. The tarnished leads are seen in a wet process (e.g., oxide wash process).

Fig. 4 Pictorial illustration of an imprint of device terminations on the gold lid of a ceramic package. The imprints are formed when the units are soaked in a sodium-hydroxide solution at an elevated temperature.

Fig. 5 Mechanism for a galvanic reaction. The terminal is in contact with a stainless steel or aluminum surface seen in (a). The presence of an acidified electrolyte completes the path that allows the charges to be transported from one dissimilar metal to the other. In this case, the solder (or tin) is the anode, which dissolves anodically with eventual consumption of the solder (seen in b). This results in a tarnished lead.

units were thrown into the sodium hydroxide solution, contacts between the terminations and the gold lid were made unintentionally. If there is a contact between the gold lid and the terminations, galvanic corrosion occurs where the tin of the lead surface is transferred onto the gold surface.

In a sodium hydroxide solution, the reaction product is $\text{Sn}(\text{OH})_2$ or $\text{Sn}(\text{OH})_4^{2-}$. The products float around the vicinity of the reaction site. If the stannous hydroxide particles are on the cathode side (gold lid), the stannous salts may be redeposited at the area of contact on the cathode (the gold lid of a ceramic device) as follows:

(redeposited at the area of the gold lid)

(redeposited at the area of the gold lid)

The ceramic body is heavy enough to make a very tight contact between the leads and the gold lids, as units are stacked randomly on top of each other. The end result is a spongy deposit of tin, which appears as a gray spot. When the soaking is further prolonged, an imprint of the terminations can be seen, as shown in Fig. 4. The concentration of the sodium hydroxide solution is 1 mol/dm³, and the temperature is kept at 50 to 60 °C (120 to 140 °F). The main application of the solution is to strip off the ink symbols. However, due to improper handling (making a contact between gold and solder), galvanic corrosion occurs.

Tarnishing due to Chemical Residues. Tarnishing of the leads occurs for the entire terminations and with different color appearance. Plating, soldering, and other wet processes tend to leave residues on the surface when the rinsing and drying are not optimized. The chemical residues are corrosive (acids or alkalis), and in the presence of temperature and high humidity, corrosion of the solder or tin surfaces is expected. There are two common types of burn-in processes: static, where the temperature is fixed (usually about 125 °C, or 255 °F), or a dynamic burn-in, where the devices are subjected to a low temperature (commonly below 25 °C, or 75 °F), then to a high temperature (about 125 °C, or 255 °F). In the static burn-in process, the chemical residues react with the solder or tin, forming oxides, with an appearance of a tarnished surface. Though a N₂-rich or a dry-air purging may be engaged, if the amount of residues is large, corrosion could still occur. In a dynamic burn-in, care should be taken to minimize the amount of moisture (the level is influenced by the percentage of relative humidity) being trapped by freezing during the cold cycle. The common method is to purge with a stream of inert gases (N₂ or clean dry air) and optimize air leakage during the burn-in process.

Non-optimization of the rinsing steps in a plating process could also result in another form of tarnishing—tinged yellow tarnished leads—after a long burn-in. Solderability is not affected,

but production flow is slowed down by the time spent deciding whether to accept the tinged appearance. It is believed that adding a neutralization step in a plating process (Ref 5) would help to minimize this tinged appearance. It is believed that the neutralization step immediately after plating helps to fill the pores of the plating layer. This means that no plating residues are trapped during the water rinsing step.

Tarnishing Caused by Base Metal Migration. Plating layers, especially those with low thicknesses, are generally porous. This means the protective efficiency is limited when subjecting the devices to a prolonged temperature treatment (e.g., burn-in). An example is copper leadframes plated with tin or a solder coating. The copper base metal migrated and reached the surface of the thin plated layer and then oxidized to a copper oxide, with its characteristic copper color. Apart from the thickness factor, the rinsing process in plating is also an important parameter to take care of. If the thin plating layer is immersed in the rinsing process for too long and at too high a rinsing temperature, the plated layer is believed to become more permeable. The copper from the base metal can easily and similarly migrate upward. Upon a thermal treatment (drying, burn-in, or other heat treatment), the copper at the plated surface gives rise to a copper color. For Alloy 42-based leadframe, the migration of nickel and iron is probable; you may see a rusty color (due to the formation of an iron oxide) on the plated layer.

Tarnishing by Plating Additives. Electroplated metals are known to be porous and may contain occluded additives, as compared with metals made by casting. If there is a breakdown in the additives, or improper current density, the plated layer may be more porous, and hence, more prone to oxidation (corrosion). The O₂ may diffuse into the porous layer, causing more oxidation, and hence, tarnishing. Occluded additives may be quantified in terms of “carbon content” and may be controlled at less than 10 ppm. High carbon content is usually found in bright plating. For semibright plating, the carbon content is relatively lower. Tarnishing is due to the gradual outgassing of the additives (moisture as a by-product) when the IC devices are aged. Thus, one needs to optimize the plating bath composition, rinsing steps, and conduct a series of stringent tests to ensure that the plated layer has a consistent built-in tarnish-resistance capability. An example of the test is to bake the plated sample at 150 °C (300 °F) for 120 h without nitrogen purge. If no tarnishing of the leads is seen, it is said that the plating baseline is optimized with strong resistance to tarnishing. Another test is subjecting the plated sample to a solder reflow process. Tarnishing of the plated layer (purple or brown appearance) after exposure to a reflow process is an indication that the plating process is not optimized.

Rusty and Multicolor Seen on the Leadframes and Package Body. This is characteristic of Alloy 42 leadframes (42% Ni and 58%

Fe), which is anodic in nature (easily corroded when wet). When the Alloy 42 leadframes are bundled together prior to plating, care is taken not to have compound and the leadframe in contact because such packing would result in an imprint of the leadframe fingers, with appearance ranging from a light gray imprint to the extreme rust color on the package body (molding compound).

In an assembly plant, one may observe multicolor rust and various shades of blue (in some assembly sites, a term referred to as “rainbow” color) on the plated terminations, plastic body of a device, or at the interface between the plastic compound and the terminations. Such rusty stains were seen occasionally after an autoclave test or at end of the line. The stains were attributed to:

- Air (with the active corrosion ingredient oxygen) not fully pumped out (due to a faulty valve in the pressure cooker test chamber)
- Chemical residues remained on the plated terminations.
- The leadframes were not annealed properly during the manufacturing of the leadframes. Stressed leadframes are more prone to corrosion, compared with annealed leadframes.

The rainbow stains or rust is a mixture of nickel and iron, based on the energy-dispersive x-ray analyses done on the stain area. The corrosion products are a mixture of nickel hydroxide and iron hydroxide.

Palladium-coated Alloy 42 leadframes are seen with rainbow-colored stain on the body and the leadframes after a 96 h pressure cooker (autoclave) test. Palladium plated on Alloy 42 is an example of a dissimilar metal pair coupled with stress generated by the trim-form process. Corrosion of the alloy occurs, giving rise to a mixture of iron and nickel oxides. Hence, it is not recommended to have the palladium on Alloy 42 for this reason. Such corrosion is not seen on the palladium-plated copper leadframes because the electrode potentials of copper and palladium are both on the noble end of the electromotive force (emf) series. The addition of another noble layer (e.g., gold) may remedy the

Fig. 6 Tarnished area of interface between the molding compound and the leadframe of a partially drawn thin-small-outline package. The color of the stain is a typical rust color (for Alloy 42 leadframe) or green color (for copper leadframe).

Fig. 7 A "fish-bone" diagram showing the causes of tarnishing of leads.

corrosion seen at the palladium-coated Alloy 42 leadframes.

Rust Stain Seen at the Interface between Leadframe and Compound. An example of corroded inner leads (Alloy 42) is illustrated in Fig. 1 (see point 2). This is due to poor adhesion between the compound and the leadframe. The chemicals (acids or alkalis) can diffuse into the package and react with the Alloy 42. The corroded products, oxides of iron and nickel, are illustrated in Fig. 6 where the stain mark is seen.

Controlling Tarnished Leads at the Assembly

Is it possible to have zero tarnish at the end of the line? Ideally, one should aim for "zero defect" tarnished leads, but practically it is difficult to achieve this without proper planning of the plating process and post-plating handling such as burn-in, oxide wash of the leads, and the washing of the burn-in board. The essential process is summarized by the "fish-bone" diagram in Fig. 7. One common factor overlooked

is the oven: air leakage is often observed as doors are not properly sealed (sealant wear off) and at outlets for piping connections. In tropical countries the air is moist with a certain high relative humidity value. If not properly controlled, tarnishing of the leads may result. Generally, the most serious cause of corrosion of the terminations seen in this industry is the plating (or flux) residues, acids, and alkalis. With time and temperature, severely tarnished leads can be observed. Generally, SIC devices are stored in a warehouse where the air humidity should be controlled at about 55 to 60% relative humidity. If there is a chemical spillage (e.g., acid spillage, acid rains, or release of hydrogen sulfide due to some industrial accident), actions need to be taken to protect the SIC devices by relocation or proper sealing of the windows and rooms.

Corrosion in Passive Electrical Components

Stan Silvus, Southwest Research Institute

THE BROAD SPECTRUM OF ELECTRICAL AND ELECTRONIC COMPONENTS can be divided into two classes: semiconductor devices (i.e., active devices) and passive components. This article concentrates on passive components such as resistors, capacitors, wound components, sensors and transducers, relays and switches, connectors, printed circuit boards, and hardware. Various types of corrosion-related failure mechanisms and their effects on electronic and electrical components are illustrated by actual field-failure examples.

Corrosion and related phenomena cause a variety of failures in electronic and electrical passive components. Although the most pervasive factor in corrosion-related failures is solder-flux residue, environmental factors play important roles also. Thus, for long-term reliability, electronic and electrical components should be kept clean (i.e., free of ionic contaminants), and they should be protected from environmental contaminants that cause corrosion or tarnish. Some corrosion mechanisms are either driven by or accelerated by electrical potential differences, but in such cases, it is actually the electric-field strength (i.e., the ratio of potential difference to physical separation) that is the ultimate driving force; accordingly, during circuit-board design, spacing between adjacent electrical conductors must be given due consideration.

Halide-Induced Corrosion

Many types of solder fluxes contain halides. Frequently, the halide constituent is the chloride ion, but in some solder-flux formulations, bromide and fluoride ions may be present alone or in combination with chloride ions. Of course, solder flux is a necessity in assembly of electronic components into systems, so the effects of halides from this source are constant considerations. Moreover, the service environment to which electrical and electronic components are exposed may contain halides. Near a seacoast, for example, the air may contain salt, or

a process fluid to which a component is exposed may contain a halide.

Wound components (e.g., relay and solenoid-valve coils, transformers, inductors, motors, etc.) contain copper wire that is susceptible to halide-induced corrosion (Ref 1). Usually, in such devices there is also an electrical potential that accelerates corrosion, but the potential is not a requirement for halide-induced corrosion of copper wire. One of the worst cases for electrical-potential acceleration of copper corrosion is the use of a wound component in a low-side-switched circuit (Fig. 1). In this frequently used circuit, one end of the coil is permanently connected to the positive side of a direct-current (dc) power supply, and the opposite end of the coil is switched to ground whenever it is desired to actuate the device. Because of the permanent connection to the power source, a low current may pass continuously through leakage-resistance paths from the copper wire to the

grounded magnetic-core structure (Fig. 2), and this current causes corrosion of the copper magnet wire and attendant removal of copper ions from the wire; the ultimate result is an open circuit in the coil.

Necessary conditions for halide-induced corrosion of the copper magnet wire in a coil include (a) a pinhole or crack in the thin polymeric insulation on the wire, (b) a halide-containing material, and (c) moisture. Typical specifications for polymer-insulated magnet wire allow as many as 15 pinholes per 100 ft of wire, so there are plenty of pinholes to satisfy one of the conditions. Because relative humidity greater than about 45% provides enough moisture to support corrosion, sufficient moisture is present except in unusually dry environments.

The most common source of halide contamination in coils is solder-flux residue. Typically, ends of the fine magnet wire in a coil are soldered to larger wires that form the coil leads. After soldering has been completed, residual flux is usually removed by brushing or spraying the joint with alcohol or other suitable solvent. In many cases the coil is not protected from flux-containing solvent drops or overspray during the cleaning operation. When no protection is provided, flux-containing liquid tends

Fig. 1 Coil in low-side-switched circuit

Fig. 2 Electrical-leakage paths in a typical relay structure (not to scale; proportions distorted for clarity)

to wick into the coil winding. As suggested in Fig. 2, the most critical locations are near grounded metallic structures, that is, inside surfaces of the coil-bobbin flanges and the bottom layer of the winding. If an insulation pinhole is present at one of these critical locations, then corrosion of the wire is likely to occur. Additionally, if an electrical potential difference exists (e.g., as in a low-side-switched circuit), then the rate of corrosion increases. Figure 3 shows a typical example of corrosion in the bottom layer of a low-side-switched relay coil. The magnet wire had been severed by corrosion at the indicated site, and corrosion products at the site contained chloride ions. The source of chloride ions was the solder flux that had been used in terminating the coil ends.

Two examples of chloride-induced corrosion of very fine magnet wire in the coil of a small magnetic sensor are shown in Fig. 4 and 5. These photographs illustrate the two common locations for coil corrosion: wires in the bottom layer of the coil (Fig. 4) and wires that touch a bobbin flange (Fig. 5). The source of the chloride ion in this case was the flux that was used when the sensor terminals were soldered to a printed circuit board. The circuit board had been cleaned after the soldering operation, but the sensor package had relatively large openings around its terminals, and flux-containing cleaning solvent

entered through these openings and wicked into the coil.

Ends of corroded wires typically have irregular shapes as illustrated by the examples shown in Fig. 6 through 8. Dangling insulation fragments (Fig. 6), hollow ends leaving insulation sheaths (Fig. 7), and very unusual shapes (Fig. 8) are commonly observed.

When coil failure is suspected, the first electrical check should be made by connecting a high-input-resistance (1 to 10 G Ω) dc voltmeter across the coil terminals. If a voltage on the order of a few millivolts or higher is present, then it is very likely that corrosion was the cause of failure. After the terminal-voltage measurement has been made, it is permissible to check coil resistance with an ohmmeter to confirm that the coil is an open circuit.

Preventive measures include: (a) careful cleaning of solder joints with protection of the coil from flux-laden solvent drops and overspray, (b) protecting the coil from human spittle, which contains chloride ions, and (c) sealing the coil against entry of flux and other contaminants during subsequent soldering and cleaning operations and field service. Additionally, in low-side-switched circuits, use of a negative power supply can eliminate acceleration of corrosion; however, chemical corrosion may still occur if the coil is contaminated, so

cleanliness remains the key to protecting coils from corrosion.

Sometimes, corrosion failures in coils are initiated by other failures. Figure 9 is an as-received view of the inside of an encapsulated coil; a package crack caused by elevated-temperature aging of the bobbin material is pointed out. Voltage measurement suggested that the coil had corroded internally, and a subsequent resistance measurement verified that the coil was an open circuit. Because corrosion was suspected, the bobbin material was removed in the vicinity of the crack to facilitate inspection of the magnet wire. A corrosion site was found against the inside of the bobbin flange (Fig. 10, 11). Microprobing of the wire showed that the site pointed out in Fig. 11 was the only break in the coil. Energy-dispersive x-ray spectroscopy (EDS) of the corrosion product detected chlorine. The failed coil had been in service near a seacoast, and it appeared that the detected chloride ions and the moisture required to support corrosion were airborne. Location of the corrosion site suggested that contaminants entered the coil through the crack in the bobbin.

Although this article deals primarily with passive devices, there are some exceptions to the division between nonsemiconductor devices and semiconductor devices. An example of a fringe-area device is a pressure transducer that

incorporates a silicon strain-gage bridge. There are four diffused resistors on a silicon strain-gage die. Two of these resistors are in a high-stress region of a thin silicon diaphragm, and the other two are in a low-stress region. Resistances of the highly stressed resistors change when pressure is applied to the thin diaphragm, but resistances of resistors in the low-stress region change very little. The function of the latter two resistors is to provide temperature compensation of the bridge. The aluminum bond pads and interconnecting metallization on a silicon strain-gage die removed from a failed pressure transducer were corroded (Fig. 12). Corrosion products, shown in detail in Fig. 13, contained

Fig. 8 Scanning electron micrograph showing unusually shaped end of corroded copper magnet wire

bromine. Further investigation revealed that the silicone-rubber seal between the process fluid and the silicon die had a leak, and this leak permitted the process fluid, which contained a water-soluble bromide compound, to contact the aluminum metallization and cause corrosion.

The connector shown in Fig. 14 had tin-plated carbon steel pins. It is evident that the pins were rusty and that some of the corrosion products had made their way to the interior walls of the connector shell. An EDS analysis of the corrosion products detected iron, chlorine, and oxygen, suggesting that both iron oxide and iron chloride were present. Information provided by the user of the connector revealed that the component had been used in a sheltered outdoor location near a seacoast; hence, it appeared that the corrosion-causing chloride ions were airborne.

Organic-Acid-Induced Corrosion

Some solder fluxes contain organic acids, and residues of this type of solder flux are probably the most common sources of organic-acid con-

tamination in electronic components. However, other materials contain organic acids or related substances that sometimes cause corrosion in electronic components.

The inside of a good aluminum electrolytic capacitor is shown in Fig. 15. A roll, comprising two specially treated aluminum-foil plates and two interleaved electrolyte-saturated paper separators, is housed in a drawn-aluminum can that has a plastic cover sealed into one end. Two aluminum terminals penetrate the cover to provide connections to external circuitry, and the plate foils are connected to the inside ends of the terminals by aluminum ribbons or tabs that are spot welded or crimped at their ends. Because the capacitor contains an electrolyte, all of the metals inside the device are aluminum so that there is no support for galvanic corrosion. Despite this single-metal construction, the capacitor shown in Fig. 16 failed because its positive tab or ribbon had corroded. The negative tab was undamaged, suggesting that the dc potential impressed across the capacitor during normal service played a key role in the corrosion process.

Fig. 9 Inside of failed coil bobbin showing crack (millimeter scale)

Fig. 10 Overall view of corrosion failure site in failed coil

Fig. 11 Detail view of corrosion failure site in failed coil

Considering that the electrolyte does not attack aluminum, it was apparent that a foreign substance was involved in the failure shown in Fig. 16. Chlorine-containing solvents are notorious for penetrating the seals of aluminum electrolytic capacitors. When such materials get inside the capacitor, they decompose, yielding chloride ions that attack the aluminum. However, in the failed capacitor, no chlorine was detected in the corrosion products. Normally, the insides of aluminum electrolytic capacitors have an aminelike (i.e., fishy) odor, but the failed capacitor had a very strong phenolic odor. It was determined that the cover was made of phenolic plastic, and the particular variety of plastic used in the cover had a phenolic constituent that was leached by the electrolyte (Ref 2). The phenolic leachant was the foreign material that facilitated electrochemical corrosion of the positive tab. Use of a different cover material was the preventive measure employed in subsequently produced capacitors.

Capacitors intended for continuous across-the-power-line service in alternating-current (ac) circuits are frequently of the metallized-polypropylene-film type. In addition to having very low power loss, these capacitors have a desirable self-healing capability if a small short circuit (e.g., at a pinhole or inclusion in the polypropylene film) occurs between opposite-polarity plates. A self-healing event, also called a clearing event, causes the thin deposited-metal coating on the polypropylene film to evaporate in a small area around the defect, thereby effectively isolating the short circuit from the rest of the capacitor. A typical cleared site is small and approximately circular. A few cleared sites are expected in a capacitor that has been in service.

A metallized-polypropylene-film capacitor is made of two long, narrow strips of thin polypropylene film, each of which is coated on one side with a thin layer of metal (the plate or electrode). A margin along one longitudinal edge of each strip of film is left without

metallization. Two such strips, aligned longitudinally and stacked, are wound tightly into a roll with the metallized side of one strip of film in contact with the nonmetallized side of the second strip and with the unmetallized margins on opposing edges of the roll. When the film is unrolled, as in a failure analysis, the two layers of film usually do not separate; that is, they remain stacked. An additional operation is required to separate the two layers (Fig. 17).

Because the very thin deposited-metal plates are translucent, transmitted-light examination of the two stacked film layers readily reveals thin spots in the metallization. Such thin spots may include normal clearing sites and areas in which metallization has been destroyed by corrosion or another mechanism. When the two stacked layers of metallized film are backlit, areas in which the metallization is intact on both layers appear dark. However, areas in which the metallization is missing from only one layer have intermediate brightness, and areas in which the metallization is missing from both film layers are bright.

Two backlit stacked layers of metallized polypropylene film removed from a good

capacitor are shown in Fig. 18. Only a few small areas of missing metallization are apparent. In contrast, the backlit film layers shown in Fig. 19 were removed from a failed capacitor that had only two-thirds of its original capacitance. In the darkest areas in Fig. 19, there was metallization on both layers of film; however, in the gray areas, there was metallization on only one of the film layers, and in the brightest areas, the metallization was missing from both layers. Large sizes and irregular shapes of the missing metallization areas and absence of film defects in these areas indicated that clearing was not the failure mechanism; corrosion of the zinc-aluminum metallization had occurred instead. Elemental analysis of areas in which the metallization was

missing did not detect halides, but did detect constituents of organic acids. Moreover, there was evidence that the spot-welded wire-lead attachments to the terminations at the ends of the metallized-film roll had been manually reworked with a soldering iron, an operation that required use of flux. Although an attempt had been made to clean the solder joints, some solder-flux residue remained. Elemental analysis indicated that the flux residue was of the organic-acid type. Leaving potentially corrosive solder-flux residue on the ends of the roll was inadvisable, but cleaning the joints with a solvent and allowing the flux-laden solvent to wick into the roll greatly accelerated the significant metallization damage that subsequently occurred.

Electrochemical Metal Migration (Dendrite Growth)

To some extent, all metals are susceptible to electrochemical metal migration. Conditions necessary for metal migration include (a) a migration-susceptible metal, (b) an ionic contaminant, (c) an electrical potential difference, and (d) moisture. Among the metals commonly used in electronic assemblies, silver, lead, tin, and copper are particularly susceptible to migration, with silver being the most susceptible (Ref 3). The most common ionic contaminant is solder-flux residue, either the halide-containing type or the organic-acid type. A potential difference is required for electronic circuits to function, so one of the conditions is always met in operating circuit boards; however, under some conditions, galvanic potentials developed between adjacent dissimilar metals may provide sufficient driving force for metal migration to occur on a nonoperating circuit board. Ditz (Ref 4) has shown that a relative humidity higher than about 43% provides enough moisture to support silver migration, and it is likely that only slightly higher humidity levels will support migration of the other metals widely used in electronic assemblies.

In the past, printed circuit boards assembled with halide-containing fluxes were cleaned after soldering had been completed. The cleaning process may have included washing the board in a suitable solvent or in deionized water, perhaps with a nonionic detergent added. Recently, however, many printed circuit board assemblies are using “no-clean” solder fluxes that are based on organic acids. The idea behind “no-clean” fluxes is that during the high-temperature reflow step of the soldering process, the corrosive constituents are either evaporated, decomposed into benign substances that may be left in place, or encapsulated in a hard shell that effectively passivates them. In the latter case, the hard shell should never be damaged; if it is damaged, the corrosive substances will be released, and corrosion may follow. Although the “no-clean” process normally goes as intended, sometimes

Fig. 17 Partially unrolled metallized-film capacitor showing individual film layers and stacked film layers (millimeter scale)

Fig. 18 Backlit view of two stacked film layers removed from a good metallized-polypropylene-film capacitor

Fig. 19 Backlit view of two stacked film layers removed from a failed metallized-polypropylene-film capacitor

solder flux wicks into the small clearances under surface-mounted components where some of the flux may be protected from heat. In this case, evaporation, decomposition, and encapsulation of the acid constituents do not necessarily occur, and the result is that a potentially corrosive material may be left in critical locations on the circuit board.

Many surface-mounted electronic components have a layer of silver in their solderable terminations. An electrolytic contaminant, such as solder-flux residue, an electrical potential difference, and moisture combine to support electrochemical migration of silver, a metal highly susceptible to this phenomenon. The resulting dendritic growth usually leads to a short circuit in parallel with the component. Figure 20 shows the back side of a surface-mounted chip resistor that failed in this manner.

As mentioned earlier, silver is not the only electromigration-susceptible metal widely used in the electronics industry. Figure 21 is a scanning electron micrograph of the area between two adjacent solder joints on the ceramic substrate of a thick-film-hybrid resistor

network. The dendrites pointed out in this micrograph are lead (Pb) that was leached from the adjacent solder joint. An EDS analysis of the substrate in the vicinities of the dendrites detected the electrolyte-forming elements sodium and chlorine. Interestingly, the dendrites did not complete a metallic short circuit between adjacent solder joints, but instead shortened the insulating path length enough to produce an unacceptably low resistance through the sodium-and-chlorine-based electrolyte film that formed on the ceramic-substrate surface.

The failing resistor-network substrate had been encapsulated in a transfer-molded plastic that did not adhere well to the metal terminals of the device. Lack of adhesion caused thin gaps at the terminal entries (Fig. 22). Moreover, the resistor network was mounted on the wave-soldered side of the printed circuit board and, hence, was immersed in chlorine-containing flux just before exposure to the thermal shock of the high-temperature solder wave. Following the soldering operation, the circuit board was cleaned in softened (i.e., sodium-containing) water. The result of this process was that

chlorine-containing solder flux and sodium-containing water wicked into the areas between solder joints by way of the terminal-entry gaps. The resulting electrolyte then supported electrochemical migration of the lead constituent of the solder.

Figure 23 is a detail view of the area between two adjacent solder joints on a printed circuit board. Tin dendrites growing between the solder joints are clearly visible. The circuit board had been exposed to a chlorine-containing flux during the soldering operation and had not been cleaned properly. Subsequently, the board was conformally coated with a clear polymeric material. Many conformal-coating materials do not adhere well to solder-flux residue, and they eventually delaminate from the circuit-board surface forming thin pockets in which moisture accumulates. The environment in these pockets becomes ideal for metal migration, and dendrites, such as those shown in Fig. 23, grow. The eventual result is a short circuit between the adjacent solder joints.

Less organized metal migration is shown in Fig. 24. In this case, the migrating metal was

Fig. 24 Copper migration and corrosion on surface of failed printed circuit board

copper, and the ionic contamination was from the organic-acid solder flux used in circuit-board assembly. There was plenty of moisture present because failure occurred during a temperature-humidity-bias (THB) test in which the relative humidity was maintained at 85%. Whether the fingerprint pointed out in Fig. 24 was present during the test was unknown. In addition to metal migration, there was a small amount of copper corrosion.

Three of the four conditions for metal migration are almost always present on electronic circuit boards, leaving ionic contamination as the only condition that may be practically controlled. For best reliability, circuit boards should be thoroughly cleaned after soldering, and cleaning is essential if boards are to be conformally coated. "No-clean" solder fluxes work satisfactorily in relatively benign operating environments, but in critical applications in which long-term reliability under adverse conditions is required, other types of flux should be used, and the circuit boards should be cleaned after soldering has been completed. In cleaning, particular attention should be given to removal of solder flux trapped under components, particularly surface-mounted devices.

Silver Tarnish

Silver is frequently used in electronic devices because of its high electrical and thermal conductivities. However, silver is highly susceptible to tarnishing in the presence of sulfur-containing materials such as airborne hydrogen sulfide and sulfur dioxide. The tarnish product, silver sulfide, has poor electrical conductivity. As the tarnishing process progresses, electrical resistance of the conductor or contact surface increases until an open-circuit failure occurs. The only practical preventive measures are to avoid use of silver in sulfur-containing environments or hermetically seal silver in an inert atmosphere.

A common source of sulfur-containing gases is vulcanized rubber, which is sometimes used for insulating electrical wires. Other sources of sulfur-containing gases include brown paper bags and cardboard boxes. If rubber objects are enclosed in the same housing with silver-containing electronic components, failure is almost inevitable. A typical example (Ref 5) is illustrated in Fig. 25, which shows a corner of a surface-mounted chip resistor that has a layer of silver in each of its terminations. The silver layer had been consumed by tarnish, and the resistor had become an open circuit. The circuit board on which this resistor and others like it were mounted had been enclosed in a poorly ventilated housing along with a vulcanized-rubber conduit that contained some of the system interconnection wiring. A sulfur-containing gas evolved from the rubber and reacted with the silver terminations of the resistor to yield silver sulfide. A scanning electron micrograph

of a cross section through the failed resistor termination (Fig. 26) shows the silver-depleted region that broke the circuit between the resistive element and the termination.

A similar failure occurred in a trimming potentiometer that was installed in a control system located in a tire-manufacturing plant where substantial concentrations of sulfur-containing gases were present. The effect of these gases was to tarnish the silver terminations at the ends of the potentiometer resistance element (Fig. 27). The silver was consumed with the result that the potentiometer became an open circuit. Figure 28 is a scanning electron micrograph showing a detail view of one of the tarnished terminations; the grasslike appearance is typical of tarnished thin films of silver.

Many relay and switch contacts are made of silver or high-silver-content alloys. In environments that are contaminated with sulfur-containing gases, surfaces of such contacts tarnish, and the contacts become incapable of completing an electrical circuit when called upon

to do so. Figure 29 shows a typical heavily tarnished silver alloy relay contact. Even though the mechanism in this relay provided desirable wiping action, as evidenced by the elongated

Fig. 27 Overall view of substrate in failed trimming potentiometer showing tarnished silver terminations

wear pattern, the wiping action was not sufficiently aggressive to break through the tarnish film that had built up over the long periods of time during which the contact had been held in the open state. Failure of this contact was caused by sulfur-containing gases that evolved from the rubber insulation on wires that were housed in the same enclosure.

Fretting

The rotor of a motor-operated switch was bound so tightly that the mechanism could no longer rotate. Inspection of the drive mechanism showed that grease in the sleeve bearings had become hard (Fig. 30), and subsequent EDS analysis detected the sleeve-material elements in the hardened grease. Disassembling the mechanism revealed additional hardened grease on the corresponding journal (Fig. 31). Cleaning the sleeve and journal, applying fresh grease, and reassembling the device restored normal operation.

The motor in the switch was operated from a 60 Hz ac source. As a result, low-level 120 Hz vibration was present while the coil was energized continuously for months at a time. The almost continuous vibration caused fretting of the sleeve bearing, and the resulting fine metallic particles led to hardening of the grease and consequent binding of the mechanism. Using dc excitation would have

eliminated the vibration and minimized the possibility of fretting of the sleeve-bearing surface.

Metal Whiskers

Of the metals frequently used in electronic devices, tin is the most likely to form whiskers. Such whiskers may be several millimeters long, and, of course, they are electrically conductive. Examples of tin whiskers projecting from the tin-plated base of an insulated standoff terminal are shown in Fig. 32. One of the whiskers on this terminal contacted an adjacent resistor lead, thereby causing a short circuit to ground. In this situation, there was not enough energy available to evaporate the whisker, so circuit malfunction ensued. However, in many circuit applications, there is enough energy available to evaporate a small-diameter metal whisker, and in such cases, whiskers usually are nuisances rather than causes of hard failures. Tin whiskers are of great concern in outer-space applications in which evaporation of a metal whisker may trigger catastrophic arcing.

It is generally thought that metal whiskers form as the result of residual stresses in plated layers, but the underlying base material also has an influence. One often suggested preventive measure is to anneal or reflow the plating. Brusse et al. (Ref 6) have published an extensive treatise and bibliography on metal whiskers.

There is a modern environmentally driven trend toward lead-free electronic components and equipment. The lead in conventional tin-lead solder alloys appears to suppress tin-whisker formation, so eliminating lead from solder takes away this desirable feature. In this regard, the National Aeronautics and Space Administration (NASA) prohibits use of pure tin and requires at least 3 wt% Pb in tin-lead alloys to suppress tin-whisker formation (Ref 7). There is evidence that other alloying elements (e.g., silver, indium, antimony, and bismuth) suppress tin-whisker growth, but the referenced NASA document does not mention these as acceptable alternatives.

Most of the proposed lead-free solder formulations have high tin content, and the solderable surfaces of many lead-free components are plated with pure tin. Thus, tin-whisker formation is resurfacing as a potential reliability concern. The IPC (formerly the Institute for Printed Circuits) Solder Products Value Council has recently published a report (Ref 8) that recommends the 96.5Sn-3.0Ag-0.5Cu composition (designated SAC305) as the alloy of choice for lead-free applications. Supporting this recommendation was an extensive round-robin evaluation that included determination of assembly-line performance characteristics, metallurgical cross sectioning, metallographic analysis, thermal cycling, thermal shock, and other tests. Apparently, however, the potential for tin-whisker growth was not assessed. At this writing, experimental lead-free solders have not been in field service long enough for accumulation of reliable statistical data on tin-whisker formation, so only time will tell whether the proposed lead-free solder alloys are really trouble free.

ACKNOWLEDGMENT

The author thanks Steve Axtell and Pat Kader, who supplied some of the key illustrations used in this article, and Ken Cook who took the remainder of the photographs. The author also thanks the peer reviewers for their many helpful suggestions.

Corrosion and Related Phenomena in Portable Electronic Assemblies

Puligandla Viswanadham, Nokia Research Center
Sridhar Canumalla, Nokia Enterprise Systems

AS INFORMATION PROCESSING ELECTRONICS migrated to homes and outdoor environments, an entirely new set of performance and reliability expectations were imposed on the products. Portable electronics comprise a host of products such as personal digital assistants, camcorders, mobile phones, external medical electronics such as hearing aids and self-diagnostic or monitoring tools, and human-portable military hardware. These products are low-cost, high-volume devices with short product development cycle as well as product life. The use profile is considerably diverse and variable. Not only do these products experience wide variations in temperature and humidity, they are also prone to exposure to condensing atmospheres and a variety of hostile gaseous and particulate contamination, particularly in urban industrial environments. As a consequence, corrosion-related exposures tend to be more prevalent in consumer and portable electronics. In addition, these products are subject to a multitude of mechanical stresses such as shock, vibration, and bend. A discussion of these mechanical aspects is considered outside the scope of this article. Nevertheless, it is important to recognize that consumer expectations of portable electronic product quality and reliability remain high.

Portable communication and entertainment are becoming the growth segments in the consumer electronics industry, and these portable electronic devices are sometimes also viewed as fashion accessories with opportunities for personalization. These devices are miniaturized, lighter, and relatively affordable at the same time. Even in the military electronics domain, the human-portable military electronic hardware has to be highly flexible, robust, and usable in a variety of environmental conditions. In general, people carry these personal portable electronic devices wherever they go, and the devices are exposed to the same environments as humans. Traditional heavy, brittle, hermetic ceramic packages that are prone to failure due to mechanical shock, vibration, and drop have

given way to lighter, low-profile, plastic packages, which are not hermetically sealed. Instead, the isolation from the environment arises from the use of primarily epoxy-based molding compounds, underfills, and so forth. Therefore, although the integrated circuits (ICs) in the electronic packages are relatively safe from moisture ingress, most portable electronic devices (appliances) are not very tolerant of environmental conditions such as condensed water, humidity, and temperature fluctuations. In addition, even low levels of corrosive substances such as chlorinated water can be lethal to electronic circuits. In this context, corrosion and related phenomena in portable electronic products are extremely important to the reliable operation of a portable consumer electronic product, and some of the salient aspects are discussed in the following sections.

Some of the metallic materials that are exposed to corrosion in electronic assemblies are:

- At the package level, materials such as aluminum, alloy-42, copper alloys, tin and tin-lead alloys, nickel, gold, palladium, and palladium-silver are employed in lead frame materials, pad metallurgies, lead finishes, etc.
- At the second level assembly where the packages are assembled onto the printed wiring board, the materials include copper, immersion tin, immersion silver, tin-lead solders, nickel, and gold.

Table 1 shows a list of typical metallurgies (and their nominal compositions) used in the various aspects of electronic packaging. Some of the salient corrosion aspects of these materials applicable to electronic packaging are discussed subsequently with emphasis placed on copper and copper alloys, tin and tin-lead alloys, and aluminum.

Owing to their portability, the electronic products considered in this article are more vulnerable to atmospheric corrosion than are traditional business and office machines. The effects of humidity and prolonged exposure to various

atmospheric contaminants are discussed in the section "Forms of Corrosion Not Unique to Electronics." Corrosion and related phenomena such as electrochemical migration and conductive anode filament formation are also important in portable electronic assemblies. These subjects are addressed in the section "Forms of Corrosion Unique to Electronics." Examples of electrochemical migration involving copper, tin, and silver are also presented.

Forms of Corrosion Not Unique to Electronics

There are a number of basic forms of corrosion that materials experience based on their nature and the environment. The various forms of corrosion, which are described in detail in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of the *ASM Handbook*, are:

- Uniform corrosion
- Galvanic corrosion
- Crevice corrosion
- Intergranular corrosion
- Selective leaching (dealloying)
- Environmentally induced cracking
- Fretting corrosion
- Hydrogen embrittlement
- Atmospheric corrosion

Depending on the severity, corrosion in electronic assemblies results in the following failure pathways:

- Oxidative materials degradation resulting in loss of electrical continuity
- Partial materials degradation accompanied by the formation of a conductive oxidation product, such as a salt, which could result in lower surface insulation resistance (SIR)
- Electrical shorts between adjacent conductive features
- Intermittent shorts or opens depending on the humidity levels and the ionic nature of the corrosion product

Relevant Forms of Corrosion

Of particular interest in electronic packaging are uniform corrosion, pitting corrosion, environmentally induced cracking, galvanic corrosion, and atmospheric corrosion (Ref 1). Atmospheric corrosion is discussed in the section "Condensing and Noncondensing Humidity."

Uniform corrosion is evenly distributed over the surface, and the rate of corrosion is the same over the entire surface. A measure of the severity is the corrosion product film thickness or the average penetration of the metal. A common example is aluminum bond pad corrosion on nonpassivated chip metallization. A metallization is defined as a single or multilayer film pattern of conductive material on a substrate to facilitate interconnection.

Pitting and Crevice Corrosion. Localized corrosion appears as pits or crevices in the metal. The bulk of the material remains passive but suffers localized and rapid surface degradation. In particular, chloride ions are notorious for inducing pitting corrosion. Once a pit is formed, the environmental attack is locally autocatalytic. Generally, pitting corrosion on the surface results in an array of pits with varying depths.

Environmentally induced cracking occurs under the combined influence of a corrosive environment and static or cyclic stress. Cracking under static loading conditions is known as stress-corrosion cracking (SCC) and cracking under cyclic loading conditions is known as

corrosion fatigue. Residual stresses in electronic package termination leads from lead forming and bending operations were observed to cause SCC failures in the presence of moisture (Ref 2). Stress-corrosion cracking of package leads was also reported in the presence of solder flux residues (Ref 3).

Galvanic corrosion is driven by the electrode potential differences between two dissimilar metals coupled electrically. The result is an accelerated corrosive attack of the less noble material. Galvanic corrosion tends to be particularly severe if the anodic surface is small compared with that of the more noble cathode, or in cases where a more noble metal is coated onto a less noble one. For instance, when porous gold plating over a nickel substrate is exposed to a corrosive environment, the gold coating acts as a large cathode relative to the small area of exposed nickel. This sets up a galvanic cell at the exposed substrate, which experiences intense anodic dissolution. Galvanic corrosion has been observed to enhance pore corrosion when the substrate metal is less noble than the coating, and vice versa (Ref 4).

Condensing and Noncondensing Humidity

In contrast to most business and office machines, portable consumer electronic hardware is subject to a much wider range of

humidity exposures owing to their portability and are therefore more prone to condensed moisture and liquid damage. The nature and amount of contamination present can influence the failure mechanisms as well. In general, dry contamination does not result in an increase in the leakage current.

While all polymeric materials are permeable to moisture and water vapor, the rate of moisture ingress depends on such factors as the nature of resin, filler material, curing agent, hydrophobic nature of filler particles, and their volume fraction, size distribution, and so forth. An important aspect in corrosion related failure is the level of extractable ionic contaminants such as chloride, bromide, and so on. Typically they are in the 5 to 20 parts per million (ppm) range. When correctly implemented, polymeric encapsulant and packaging materials have been shown to provide thousands of hours of reliable performance under biased humidity conditions. Strong interfacial adhesion, low ionic contamination in the encapsulant, and good cleanliness ensure good corrosion resistance.

Condensed moisture is likely to be acidic in nature due to the dissolution of ambient gases such as carbon dioxide, oxides of sulfur, and oxides of nitrogen. The surface morphology of the area affected will generally contain reaction products due to the corrosion and the formation of unique metal migration species.

Atmospheric Corrosion. Extended exposure of portable electronic hardware to urban atmospheres is a concern of considerable importance in terms of product performance and reliability. Reaction products of pollutant species such as sulfur dioxide (SO₂), nitrogen compounds (NO_x), hydrogen sulfide (H₂S), chlorine-containing species, mercaptans, and organic sulfur compounds can be detrimental. Some airborne nitrates tend to be hygroscopic at humidity levels above 50% relative humidity (RH) and are known to cause electrolytic SCC of nickel-brass (Ref 5). While electrical performance degradation can be caused by the electrical leakage through moisture films in the conductor interspaces, concomitant corrosion of the anodic conductor also disrupts the current flow, which can sometimes be accompanied by metal dendrite growth. The chlorine, NO₃, and SO₄ anions are often associated with corrosion susceptibility, leading to increased leakage currents causing open circuits with thin film conductors (Ref 6). Temperature, relative humidity, pollutant and particle concentration, and sample orientation are perhaps the most important aspects in the evaluation of portable electronic hardware for corrosion in an urban environment. Researchers (Ref 7) evaluated the indoor corrosion of copper, nickel, cobalt, and iron in urban atmospheric conditions. Outdoor corrosion products are generally complex mixtures of hydroxides, sulfates, carbonates, and chlorides in the case of copper metallurgy. In the case of silver metallurgy, the products are silver sulfide, hydroxide, chloride and nitrate. Nitrogen dioxide (NO₂) is a precursor to nitrous and nitric acid and

Table 1 Typical metallurgies used in electronic packaging

Category	Metallurgy	Typical composition
Wire bonding	Aluminum	Al with 1% Si Al with 1% Mg
	Gold	Au with 5 to 10 ppm Be Au with 30 to 100 ppm Cu
Die attach materials	Tin alloys	92 Sn-8Sb
	Lead alloys	95Pb-5Sn 97.5Pb-1.5Ag-1Sn
	Gold alloys	98Au-2Si
		8Au-12Ge 80Au-20Sn
Lead frame materials	Copper alloys	Cu-0.1Zr Cu-2.35Fe-0.03P-0.12Zn (Cu + Ag)99.8-0.11Mg-0.6P
		58Fe-42Ni
		53Fe-17Co-29Ni
		63Sn-37Pb
Solders	Tin-lead alloys	90Pb-10Sn 95Pb-5Sn
		Sn-Bi
		Sn-3.8Ag-0.7Cu and other variations with minor elements such as Sb, Bi
		63Sn-37Pb
PWB surface finishes	Solders	63Sn-37Pb
	Tin	Matte Sn or immersion Sn
	Lead-free alloys	Sn-Ag-Cu
	Silver	Immersion Ag with additives
Component lead terminations	Nickel-gold	Electroless Ni-immersion Au
	Nickel-gold	Plated Au
		Electroless Ni-immersion Au
		Pure Sn plating
		Ag-Pd
		Ni-Pd
		Ni-Pd-Au
		Ni-Pd-Ni-Ni-Pd-Au
Connector metallurgies	Copper alloys	98Cu-2Be
		Cu-(3.5-10)Sn-1P

its concentration is generally high in urban atmospheres. Table 2 compares the pollutant concentrations in indoor and urban atmospheres (Ref 7).

Hostile environmental test conditions can consist of H_2S , NO_2 , SO_2 , S_x , and Cl_2 species in the concentrations indicated subsequently. While most component tests are done at 70 °C (160 °F) and 70% RH, machine testing is done at 25 °C (75 °F) and 70% RH with the pollutant concentrations in parts per billion (ppb) of 350 ppb of SO_2 , 3 ppb of Cl_2 , 500 ppb of NO_2 , 0.5 ppb of S_x , and 44 ppb of H_2S (Ref 8).

Forms of Corrosion Unique to Electronics

Electronic packaging is a hierarchical structure that allows a central processing unit to communicate with memory and input/output units such as display, keyboard, and data storage devices. The packaging integrates:

- Chips into single chip modules (SCM) or multichip modules (MCM), which are sometimes known as first-level package
- Components (SCMs, MCMs, connectors, discretes such as resistors, capacitors, inductances, etc.) on a printing wiring board (PWB) that may be referred to as second-level package
- PWB assemblies, cables, power supplies, cooling systems, and peripherals into a frame or a box and termed a third-level package

The chip or integrated circuit (IC) device is connected to its carrier in one of many ways. In one scheme, the back side of the chip is bonded to the substrate with an adhesive or a solder, and the bond pads on the active side of the chip are connected to the bond pads on the carrier with a gold or aluminum wire with ultrasonic or thermocompression techniques. In another scheme, called flip chip attach, the chip is placed upside down with the active side facing the carrier and is attached to the carrier with either solder balls or gold bumps. This scheme provides the highest interconnection density for a given area and electrical performance. The entire interconnection structure, except for the termination leads, is either encapsulated with a molding compound or encased in a metal. The leads are formed in such a manner as to facilitate either insertion into the corresponding holes or

surface mounted onto the corresponding foot prints.

The first-level packages are assembled onto the PWB either by insertion mounting technology with a wave solder machine or a surface mount technology with a solder reflow oven. The reader is referred to the excellent resources on this subject in the selected references at the end of this article.

In addition to the universally observed forms of corrosion that are not specific to electronics applications, there are two other corrosion-related phenomena that are found only in electronics, namely, electrochemical migration (ECM) and conductive anodic filament formation (CAF).

Electrochemical Migration (ECM)

In ECM, which is generally observed under the influence of applied direct current bias voltage, oxidation of the metal occurs, as in the case of corrosion, at the anode. The positively charged ion, under the influence of the applied potential, travels through the electrolyte medium between the conductors toward the negative electrode (i.e., at the cathode). At the cathode the positively charged ions are reduced to neutral metal atoms. As the reduction process at the cathode continues, filamentary metal dendrites form, extending back toward the source anode. The filament growth continues until the anode is depleted, or until an electrical short occurs when the dendrites reach the anode. The following conditions need to be met for ECM to occur: (a) the presence of exposed metal, (b) sufficient moisture to form an electrolyte, (c) presence of ionic contamination for a conductive path between the anode and cathode, and (d) an applied potential.

Dendritic growth can occur between any two conductors on or in a PWB. It could be on the surface or internal to the PWB. The risk or failure locations can be at any of the following locations (see Fig. 1 for an explanation of these terms):

- Trace to trace
- Trace to pad
- Pad to pad

Fig. 1 Schematic of a printed wiring board explaining the different components that can be affected by electrochemical migration

- Plated through hole (via) to inner plane
- Plated through hole to plated through hole (via to via)

The amount of moisture required to facilitate ECM depends on the nature of the substrate, its ability to absorb moisture, and the surface topography and roughness. At the same RH, hydrophobic materials acquire fewer monolayers of moisture than hydrophilic materials. Hence, more moisture collects on hydrophilic materials and they tend to promote ECM. Exposed epoxy-glass is much more hydrophilic than a PWB surface covered with protective coatings. Exactly how many monolayers are needed to promote ECM is a matter of considerable debate. A few layers to several hundred layers have been proposed. While a few monolayers are adequate to promote ion transport on certain surfaces, others might require more monolayers. It is generally believed that the behavior of 200 monolayers of moisture closely matches the bulk behavior. Both adsorption, which is a surface phenomenon, and absorption, which is a bulk phenomenon, play crucial roles. Surface defects, such as cracks and crevices, modify the ECM due to capillary action.

If the PWB material under consideration is porous, moisture penetrates into the bulk and can lead to vertical migration. Nucleation sites are required for dendrites to initiate and grow. Surface roughness, presence of sharp corners, kinks, and so forth provide such nucleation sites.

Applied voltage, while providing the necessary potential for the anodic and cathodic reactions, also provides the driving force for the ion transport to their respective electrodes. Most consumer electronics operate in the 3 to 15 V range. Higher voltages accelerate the ion transport. Dendrite formation as a function of voltage was studied (Ref 9). At low voltages of 2 to 4 V, the time to failure versus voltage followed the log-linear form of the Butler-Volmer equation (Ref 10). At higher voltages the time to failure saturates at a specific value and becomes transport limited.

As consumer electronic products migrate toward finer pitch packages, the spacing between conductors becomes smaller, approaching 50 to 75 μm (2 to 3 mils) wide lines and spaces. Thus, the voltage gradients become steeper compared with coarse pitch circuitries. In the presence of steeper voltage gradients, ionic species migrate faster to their respective electrode, hastening the times to cause potential product failure by ECM. As the thrust toward miniaturization continues and finer pitch packages come into use, the surface cleanliness of the PWB assemblies will become an important challenge. Assemblies thus become less tolerant to even minute amounts of residues containing ionic contaminants.

Dendrite formation as a function of conductor spacing also was studied using water drop test (Ref 9). Time to failure was studied with lead spacing in the range of 62 to 325 μm (2.5 to 13 mils). Time to dendrite growth was found to increase monotonically with lead spacing. The

Table 2 Comparison of typical indoor and outdoor pollutant concentrations

Species	Indoor, $\mu g/m^3$	Outdoor, $\mu g/m^3$
SO_2	12.2	17.6
NO_2	26.0	43.5
NH_3	14.9	10.0
Reduced S	0.48	0.48
Cl gases	0.2	1.5
Airborne dust	16.0	61

Source: Ref 7

nature of the ionic contaminant has by far the most significant impact on dendrite growth. The severity depends on the particular ionic species involved, its mobility or transport number, ionic radius, electronegativity, electron affinity, charge to size ratio, and so forth. In PWB assemblies, the source of ionic contaminants that make up the conductive medium is generally traced to activators in the flux. These may be acid functional groups such as those found in abietic, tartaric, succinic acids, and so forth or halides such as chlorides, bromides, and the like. Tall oil water white gum resins contain diterpenic acids, esters, and monoether alcohols. During the package-to-board interconnection reflow process, autooxidative polymerization and/or degradation, disproportionation, and/or free radical chain reactions are known to take place, giving rise to complex reaction products. Halide ions such as chloride, bromides, organic acid groups, and so on can remain entrapped on the PWB due to inadequate cleaning. Also, some of the chloro-fluorocarbon-alcohol mixtures that are used as cleaning solvents decompose to give rise to hydrogen chloride at elevated temperatures. Active metals such as zinc and magnesium are known to catalyze the decomposition reactions. Subsequently, the hydrogen chloride attacks the metals with the liberation of the corresponding salts and hydrogen.

Conductive Anodic Filaments (CAF)

Another corrosion-related aspect unique to electronics is conductive anodic filament (CAF) formation. As in the case of ECM, anodic oxidation is a precursor to this phenomenon. A current leakage is observed between conductors on the same layer of the PWB or between conductors of adjacent layers. Several factors contribute to the leakage current between conductors separated by a dielectric medium. Because the PWB is made up of epoxy resin, glass fibers, and plated and etched copper traces, the final leakage current is made up of several contributions and aided by environmental factors such as temperature, humidity, and nature and extent of contamination. The degree of cure of the polymer and the porosity of the material can have significant impact on the leakage current. As discussed earlier, ECM can occur either along the surface of a PWB between any two biased conductors, referred to as surface migration, or it can occur between conductors separated by a dielectric medium, known as vertical migration. Both phenomena are observed. The moisture trapped in the pores of the surface in the presence of ionic contamination promotes migration. In a normal FR-4 printed circuit board, several interfaces exist. There is a copper-resin interface, a glass-resin interface, and a glass-silane interface if silane-coupling agents are used as glass-epoxy adhesion promoters. These interfaces can degrade under mechanical stresses, temperature, and/or humidity. Inherent interfacial mechanical stresses may be relieved under temperature and

humidity conditions resulting in interfacial debonding. Interfacial degradation provides opportunity for moisture entrapment and formation of electrochemical cells.

The anodic oxidative dissolution and the cathodic reduction reactions also induce an acidity or alkalinity gradient in the migration path. In other words, the pH (a measure of the hydrogen ion concentration) continually changes along the path. At the anode, an oxidation reaction takes place. In cases where sufficient moisture is present and is trapped along the defect interfaces, electrolysis of water occurs at the anode, generating hydrogen ions and oxygen evolution according to the equation:

A reduction reaction occurs at the cathode accompanied by hydrogen evolution and hydroxyl ion generation according to the equation:

Thus, there exists a pH gradient between the two electrodes. The metal in question will undergo oxidation to give a positively charged ion M^{n+} that migrates toward the cathode, according to the equation:

As the metal ions migrate toward the cathode, they precipitate at the point in the pH gradient where the pH promotes the precipitation of insoluble corrosion products. This point is determined by the thermodynamics of the corrosion product solubility reactions. The filament grows toward the anode as time progresses. These filamentary growths are termed CAFs when the corrosion product is conductive and is formed due to the anodic reaction. These have been known to form at the fiber and the epoxy interfaces (Ref 11). Conductive anodic filaments are generally formed in glass fiber-reinforced composites, which have propensity for interfacial damage due to temperature and humidity.

Thus, the conditions necessary for the CAF formation are:

- High temperature
- High humidity
- Interfacial degradation in the PWB (copper/epoxy, epoxy/glass)
- Applied voltage
- An acidity (pH) gradient between the two electrodes
- Precipitation of the reaction product leading to filamentary growth

Corrosion of Some Metals Commonly Found in Electronic Packaging

Copper. In most instances, the copper surface on the PWB is protected with organic solder preservatives such as benzimidazoles,

benzotriazoles, polyalkylbenzimidazoles, and so forth, until component assembly is performed. These surface coatings are extremely thin and are prone to damage due to mechanical abrasion and to instability in thermal exposures. After the interconnection process, exposed copper surfaces can experience corrosion and have the potential for product failures.

Copper and its alloys react readily with ambient air (Ref 12, 13). In the absence of moisture, a thin layer of thermodynamically stable cuprous oxide grows on copper according to the equation:

The growth kinetics are parabolic at ambient temperature for about 100 h and linear thereafter. A layer of 10 nm is formed in about 10 days and has 5×10^{-8} moles of $\text{Cu}_2\text{O}/\text{cm}^2$.

In the presence of moisture and CO_2 , a green patina is formed on copper according to the equation:

This green patina can form an impervious barrier to further ingress of moisture and CO_2 and provides a permanent light green coating on copper. This patina sometimes provides an architectural appeal for buildings with copper sheet roofing and is sometimes referred to as architectural weathering (Ref 14).

Tin and Tin-Lead Alloys. Until recently, the most prevalent interconnection alloy in the electronic industry has been the eutectic tin-lead alloy with 72 at.% Sn and 38 at.% Pb that melts at 183 °C (361 °F). The corrosion reactions of solder alloys with ambient air and moisture are governed by thermodynamic and kinetic factors. Solder quickly reacts to form a tin-oxide layer when exposed to low oxygen partial pressures of 0.1 torr. At relatively higher oxygen pressures of 1 torr, a lead-rich oxide exists initially and quickly becomes tin-rich in the early stages of oxidation. Subsequently, stannic oxide (SnO_2) is the primary component with the remaining tin evenly distributed as tin and stannous oxide (SnO). The lead species are distributed evenly as lead and lead-oxides. Thus:

and

The enthalpy, ΔH^0 , for reaction in Eq 7, is -56.7 kcal/mole and accounts for diffusion of tin to the surface and results in the formation of layers that are alternatively rich in tin and lead. Differences in oxidation behavior between lower and higher oxygen partial pressure environments are kinetic. At higher oxygen partial pressures, surface tin is rapidly consumed followed by oxidation of lead. At lower oxygen partial pressures, the tin oxidation rate is lower than the

tin diffusion rate from the bulk to the surface (Ref 15, 16). In an Auger electron spectroscopic study of oxidation of molten solder, de Kluizenaar reported that a complex oxide layer is formed on clean eutectic Sn/Pb solder surface (Ref 17). It consisted of (a) a thin layer of SnO₂ about 2 nm thick, (b) a layer of SnO mixed with finely dispersed metallic lead, and (c) a transition layer of tin and metallic tin and lead. The tin oxide concentration decreased with depth into the solder while the tin metal concentration increased. Below the oxide layer was the underlying solder alloy (Ref 17).

The following reactions are possible with moisture and the solder constituents:

with ΔH^0 values of -10.6 and -22.4 kcal/mole, respectively. It can be seen by the larger negative value of the enthalpy that the tin reaction is favored and, hence, the OH species is associated with tin rather than lead.

Almost all portable electronic appliances are exposed to outdoor atmospheres including the urban industrial environments in metropolitan areas. The atmospheric pollutants include such gases as oxides of nitrogen, oxides of sulfur, hydrogen chloride, hydrogen sulfide, and so forth. The corrosive reactions encountered can be significant in the performance of portable electronic appliances.

Dry NO₂(g) promotes oxidation of the solder surface, without attendant nitrogen species on the solder surface, according to the equations:

and

with the corresponding enthalpies of, -38.9 , -74.2 , -0.2 , and -56.9 kcal/mole, respectively. In the presence of moisture, however, both NO⁻ and NO₂⁻ are formed according to the equations:

with lead nitrate as the primary product (Ref 18, 19). The square in Eq 14 represents vacancy in the lattice.

Metallic lead on the surface of solder alloys is readily covered by a tenacious adherent layer of oxide according to the equation:

However, in the presence of moisture and chlorides, lead oxide is converted into loosely adhering PbCl₂(s) as follows:

When H₂O(l) and CO₂(g) are present, lead chloride is converted to porous lead carbonate according to:

The porosity of lead carbonate facilitates further oxidation of lead according to Eq 17 until all the lead is consumed.

Aluminum. In first-level packaging, failures due to corrosion can result in electrical opens in lead wires, electrical shorts due to dendrite growths, metal migration, peeling, as well as assembly parametric changes or degradation. As indicated earlier, chloride and bromide ion contamination is not uncommon in plastic encapsulated microelectronics. In the presence of moisture and applied potential, the aluminum pad metallization can become a hydrated aluminum hydroxide. Chloride ions, hydroxyl ions, and water molecules compete for available bonding sites on the hydrated aluminum hydroxide surface. Chloride ions react with aluminum hydroxide according to the equation:

Subsequently, the chloride ion reacts with the exposed aluminum as:

The tetrachloro-aluminum ion reacts with water liberating hydrogen and chloride ions and aluminum hydroxide as follows:

Thus, the chloride ion is regenerated, and the aluminum oxidation process continues until all the aluminum is consumed.

A case of galvanic corrosion is encountered sometimes with aluminum and gold components. Aluminum, being the less noble metal, corrodes more readily, forming aluminum oxide.

Ball bond corrosion at elevated temperatures is sometimes encountered in aluminum and gold at the package level due to the presence of bromine in the flame retardant of the polymer molding compound. At temperatures above 150 °C (300 °F), the brominated compounds undergo decomposition and disproportionation reactions giving rise to a variety of corrosive species such as hydrogen bromide and aliphatic alkyl bromides.

Researchers (Ref 20) proposed the following reactions:

and

The time to failure due to these corrosion reactions depends on the time it takes for the moisture and the corrosive species to penetrate to the interfaces of importance. Defects such as cracks, crevices, voids, and so forth, already present in the structure due to other process deficiencies, will accelerate the rate of penetration.

Examples from Electronic Assemblies

Corrosion of Gold-Plated Connectors.

Gold plating of connectors is a common practice designed to protect the underlying copper and nickel layers from corrosive attack and also promote good electrical contact. However, under the action of friction, the relatively thin and inert gold coating can be removed locally, thereby exposing the copper and nickel layer underneath. In such cases, fretting corrosion, pitting corrosion, and localized galvanic corrosion can occur simultaneously, especially in the presence of ionic species such as chlorides. The resulting corrosion product, which is usually nonconductive, can cause electrical failure due to open or intermittently open contact. An example of gold-plated connector corrosion from a device exposed to field conditions is shown in Fig. 2. The energy-dispersive x-ray analysis (EDX) elemental map for gold indicates that the gold coating is intact over the major portion of the surface. However, in the central portion of the image, the gold and nickel coatings have been removed completely, and the underlying copper is exposed, identified as the bright and gray areas in the copper elemental map. The shape and size of the gray area in the center of the exposed copper area coincides with the gray and bright areas seen in the maps for oxygen and chlorine, respectively. It can be surmised that the central area of the exposed copper substrate (gray area in copper EDX map) is covered with corrosion products containing oxides and chlorides of copper, which attenuates the copper signal in the EDX map. The absence of any areas with high concentrations of nickel indicates that the mating surface of the connector has probably worn through the nickel layer in the area of contact.

Electrochemical Migration. In several studies, the propensity for ECM of different metallization systems can be ranked as follows: Ag > Pb > Cu > Sn (Ref 21). Although ECM phenomena have been observed with many metals, only silver (Ref 21, 22), and copper to a limited extent (Ref 23), and perhaps tin (Ref 24), have been found to exhibit this behavior in the presence of noncondensing but humid conditions. Indeed, it was concluded (Ref 25) that silver migration presents the greatest risk because dendritic growth can occur on ceramic and plastic substrates whether silver is outside the package and fully exposed to humid air or inside

and only partly exposed. Although researchers (Ref 25) suggested that copper migration and tin migration did not pose as large a risk, in mobile electronic products, which see a wide range of corrosive species during their lifetime, ECM of copper and tin can be as prevalent as silver

migration. In addition, residues on the substrates that originate from the PWB assembly process play an important role through water adsorption and conductivity behavior modification.

It was noted (Ref 26) that in practice, ECM could manifest itself as two separate, though

not always distinct, effects that lead to impairment of the circuit's electrical integrity. The first kind, dendritic or filamentary bridging between the anode and cathode, has been discussed at length before. The second kind of ECM is colloidal staining, which can also cause a short. Deposits of colloidal silver, copper, or tin have been observed to originate at the anode without necessarily remaining in contact with it. One example each is provided next for ECM phenomena involving copper, tin, and silver.

Copper ECM. Copper forms complex species such as CuCl_4^{2-} , $\text{CuCl}_2(\text{H}_2\text{O})$, $\text{Cu}(\text{H}_2\text{O})^{2+}$, and so forth in the presence of halide-containing species and moisture. An example of copper ECM resulting in copper dendrite formation is shown in Fig. 3 for a device exposed to temperatures ranging from 10 to 55 °C (50 to 130 °F) in a humid atmosphere of 95% RH. If copper plated through-hole vias or copper-conductor pads are too close, ECM can occur when the assembly is exposed to humid environments in the presence of an ionic contaminant.

The tin ECM mechanism is similar to that of copper, but it is much more prevalent because tin constitutes a major portion of several commercial solder compositions such as 62Sn36Pb2Ag, 90Pb10Sn, and Sn3.5Ag0.7Cu (see also Table 1). In addition, exposed tin is more widespread on an assembled PWB as compared with copper. The example shown in Fig. 4 is from a test vehicle that failed upon exposure to a similar temperature-humidity environment as in the copper ECM example. In this case, the potential difference between the terminals of a capacitor with tin terminations resulted in the migration of tin from the anode toward the cathode across the dielectric material (gray area) between the tin terminations (bright areas) in the left side of Fig. 4. The right side of Fig. 4 shows a higher magnification view of the tin dendrites at the cathode end of the termination.

The composition of the ECM products can be revealed by elemental analysis mapping data of the surface of the same capacitor as shown in

Fig. 2 Corrosion of gold-plated connector along with energy-dispersive x-ray analysis elemental maps of Au, Cu, O, Ni, and Cl

Fig. 3 Copper electrochemical migration on a printed wiring board subjected to high-humidity heat exposure

Fig. 4 Electrochemical migration on a capacitor with tin termination. The right side of the figure shows a higher magnification view of the dendrites at the cathode end of the termination.

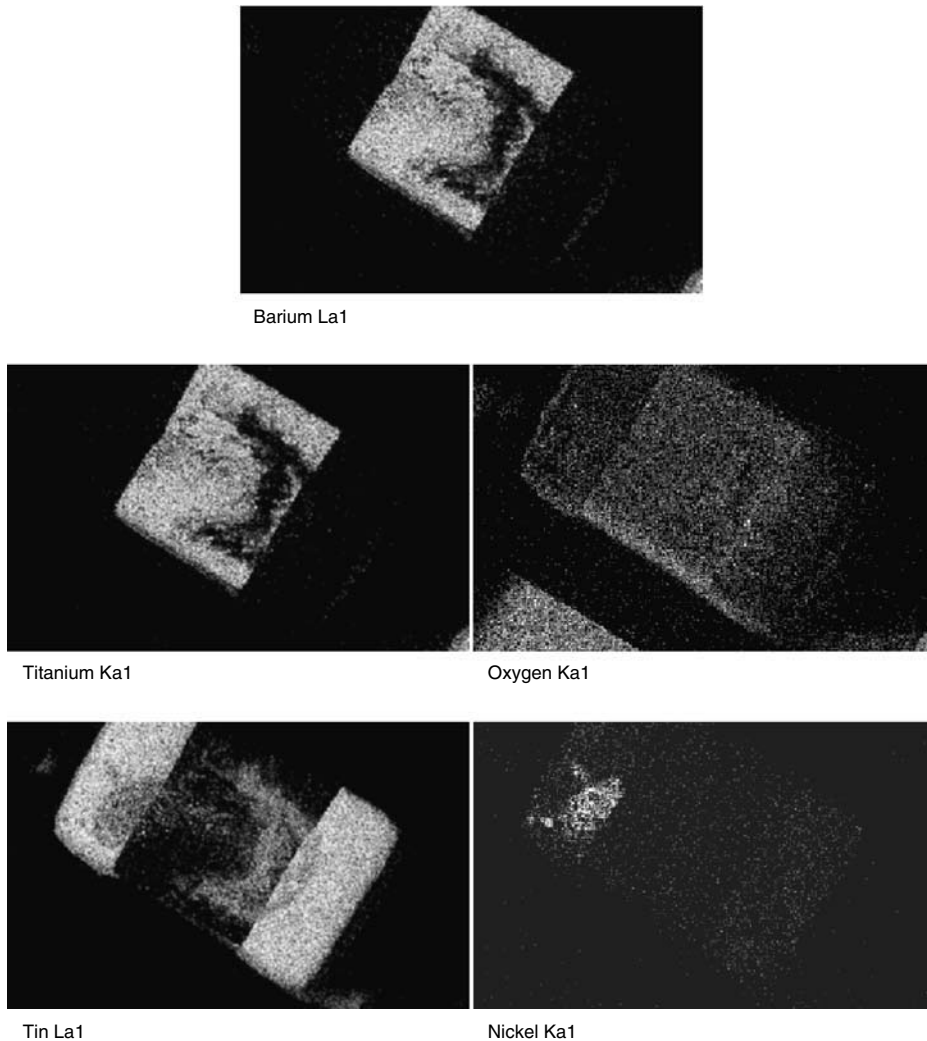

Fig. 5 Composition of the electrochemical migration product of the capacitor shown in Fig. 4. Energy-dispersive x-ray analysis elemental maps are Ba, Ti, O, Sn, and Ni. These maps show the presence of tin electrochemical migration between the terminations and exposure of the nickel barrier layer under the consumed tin surface at the anode.

Fig. 6 Tin electrochemical migration (ECM) involving both formation of dendrites and colloidal form of ECM on a resistor with pure tin termination.

Fig. 5. The capacitor dielectric material is composed primarily of barium titanate, and the barium and titanium maps show the extent of the exposed dielectric surface. For the capacitor to function, it is necessary that the cathode and anode terminations are electrically insulated from each other. Therefore, in a functional capacitor, one would not find any tin covering the dielectric material between the terminations (gray area in Fig. 4). However, in this failed capacitor, in addition to the tin at the terminations, which is normal, the tin map also shows the presence of tin between the terminations, where there should be none.

In several passive components (capacitor, resistors, etc.), nickel is used as a barrier layer between the silver adjacent to the dielectric and the tin termination. In this particular case, the nickel barrier layer at the anode is visible in areas where the tin from the surface has been consumed by the ECM process, exposing the nickel barrier layer underneath the tin. Another example of tin ECM is shown in Fig. 6, where a colloidal form of ECM can be observed in addition to dendrite formation.

Silver ECM can occur on the PWB if there is exposed metal in the termination or pad finish, or it can occur on the surface of passive devices separate from the surface of the PWB. The occurrence of ECM on the surface of passive devices can potentially be a more serious reliability risk because of the current trend toward smaller-size passives, which provides a ready site for ECM. Furthermore, silver commonly coats the ends of the passive device to ensure that there is a good contact between the electrodes in a capacitor and the termination, which is often made of tin. Therefore, nickel is used as a barrier layer between the silver base and the tin outer layers. If the nickel layer is not continuous or if there are gaps through which silver can be exposed to the environment, silver ECM can occur, as shown in Fig. 7. Here, dendrites of

Fig. 7 Silver electrochemical migration on a resistor with tin termination. Inadequate protection due to poor quality nickel barrier layers enabled the silver to exhibit electrochemical migration.

silver can be seen growing on the surface of the passive component after temperature-humidity tests.

Future Trends

As portable consumer electronic hardware becomes more complex with multitudes of functions and increased data handling capacity, further miniaturization and higher levels of integration at all levels of packaging are a natural trend. More functions will be integrated into the device. The silicon device thickness will be in the range of 40 to 50 μm . Stacked devices and folded and stacked packages will be more prevalent with a combination of multiple levels of wire bonding and/or flip chip interconnection. Another emerging trend in packaging is the three-dimensional integration at the wafer level. New materials that will have better mechanical properties and moisture resistance will be developed. More functions will be embedded into the PWB and these may include active, passive, and optical devices, attendant with new embedded interconnection schemes. The PWB technology itself will witness revolutionary changes with thinner and improved materials capable of 10 to 25 μm (0.4 to 1 mils) vias, 10 to 20 μm (0.4 to 0.8 mils) lines and spaces, and structures involving several layers of stacked vias. Consequently, hitherto unknown failure mechanisms are likely to be encountered. As the feature sizes diminish, the distinction between first- and second-level packaging becomes less clear. Failure analysis, even at the PWB assemblies, will be a formidable challenge. With shorter product development cycles and faster-to-market business environments, the need for more automated analytical tools with minimal operator intervention for rapid and repeatable root cause analysis will increase. The reliability demands will be higher to ensure customer satisfaction and product acceptance. Innovative reliability test practices will be needed to shorten the test durations to accommodate faster development schedules. The implications for reliability, failure, and root cause analysis will be significant.

As miniaturization and integration continue in portable electronic appliances, there will be increasing emphasis on new materials developments to meet performance demands. As the products become smaller and lighter, the need for thinner and lighter materials will increase. Simultaneously, better high-strength plastic composite materials will be required in order to meet the form factor and robustness requirements. As portable electronic hardware is more likely to be exposed to hostile environments, such as condensing and noncondensing humidity, and corrosive gases, than traditional business and office machines, better hydrophobic materials, and more chemically inert materials will be in demand. The electronic components and packages inside the mechanics

will be smaller, lighter, and low profile. This implies that the amount of molding compound surrounding the devices will be thinner and could be less impervious to corrosive elements. Thus, the need for better encapsulating molding compounds that are more impervious to corrosive elements will be felt. Molecular level coatings may be required for protection against corrosion and ECM on the PWBs.

Static charge and the propensity for particulate dust attraction could also be a concern in product performance. Particulate materials can act as nucleation sites for aiding corrosion reactions. New antistatic materials may be needed for adequate product protection.

The recent enormous interest and developmental activities in the area of nanomaterials and technology show considerable promise and application potential in portable electronics. Developments in nanotechnology are occurring along various fronts. These include development of high-strength composites, abrasion-resistant materials, displays, semiconductors, fuel cells, and so forth. It can be expected that the developments in nanotechnology will be extensively applied in addressing corrosion-related issues in portable electronic assemblies.

Effects of Process and Environmental Variables

Revised by Bernard S. Covino, Jr., National Energy Technology Laboratory

TWO CHEMICAL PROCESSING PLANTS making the same product and using the same or a similar process will sometimes have different experiences with corrosion. At one plant, a steel pipeline may last for many years in a given service, yet a seemingly identical pipeline may fail within weeks or months in the same service at another plant. A major piece of equipment may suddenly fail after 15 or 20 years of service as a result of less than 1 ppm of metal ion contamination in a new source of raw material.

In designing a chemical processing plant, considerable attention is paid to fluid flows, sizing of lines, pumps and processing equipment, and temperatures and pressures. Materials are selected on the basis of past experience, corrosion tests, corrosion literature, and the recommendations of materials suppliers. The nominal compositions of process streams and raw materials are known with some accuracy. Occasionally, however, other variables exist that can cause corrosion failures. The purpose of this article is to bring those variables and their effects to the attention of the corrosionist. As such, Table 1 lists

some of the variables that can affect the performance of metals in corrosive environments and gives an indication of their effect on seven different metal groups: carbon steels, austenitic stainless steels, nickel and nickel-copper alloys, nickel-chromium-molybdenum alloys, titanium, zirconium, and copper and copper alloys.

Plant Environment

One factor that is occasionally overlooked is the surrounding environment. This includes ambient temperature and composition. Temperature can be affected by geographic location (see the section "Seasonal Temperature Changes" in this article), location next to a hot or cold process, and so on. The composition of the environment can be affected not only by what is released in the plant but also by what is released by other plants in close proximity. Temperature and atmospheric composition primarily affect the external surfaces of the plant and plant equipment, causing corrosion that must be repaired periodically.

Cooling Water

The quality of water used to cool shell and tube heat exchangers can vary from season to season and year to year, particularly if the water is taken from a river that discharges into seawater. Water composition, especially chloride, metal impurities, and dissolved oxygen, can greatly affect the corrosion of equipment.

Steam

The corrosive properties of the steam used in a plant are seldom considered, particularly if the steam will be supplied by a public utility or power plant that has good boiler water treatment that will prevent condensate corrosion. However, impurities in steam can cause corrosion problems.

Water Content. One of the most important process variables, from the corrosion viewpoint, is the amount of water in a process stream. The water may be present as water vapor in a gas

Table 1 Effects of process variables on corrosion of metals in aggressive environments

Process variable	Carbon steels	Austenitic stainless steels	Nickel, nickel-copper alloys	Nickel-chromium-molybdenum alloys	Titanium	Zirconium	Copper, copper alloys
Velocity							
Increasing	> (a)	0 to >	0 to >	0 to >	0(b)	0	>
Decreasing	< L(c)(d)	< L	0 to <	0 to <	0	0	<
Aeration	>	0 to <	>	V(e)	0 to <	0	>

Sulfur compounds	V	0, SCC if S(n)	>	0, SCC if S	0	0	>

(a) >, generally increases attack. (b) 0, generally has no effect on metal in question. (c) <, generally decreases attack. (d) L, local attack or crevice corrosion is possible. (e) V, may increase or decrease attack, depending on specific alloy and environment. (f) HE, hydrogen embrittlement is possible. (g) SCC, stress-corrosion cracking is possible. (h) E, embrittlement. (j) H, hot (from 80 to 150 °C, or 175 to 300 °F, depending on variable and alloy). (k) Except in fuming HNO₃. (m) Except for dilute solutions. (n) S, sensitized by heat treatment

stream or may be soluble. Water is most likely to contribute to corrosion when it is present as a separate liquid phase. When the water is present as vapor, it is likely to condense at cold spots, such as pipe supports welded directly to process piping or nozzles in the top or vapor phase of reactors, even though the lines and nozzles are insulated.

Aeration. The design of the plant and, in particular, equipment selection can influence the amount of air introduced into a process stream, which in turn may profoundly affect corrosion. This can account for different corrosion experiences in plants having otherwise identical chemistries and products. In different cases, the quantity of introduced air can be either beneficial or detrimental. Increasing the amount of air can increase the corrosion rate of mild steel components, but reducing the amount of air may transform a normally passive stainless steel piece of equipment to a state of corrosion.

Startup, Shutdown, and Downtime Conditions

Startups and shutdowns are variables that can easily be overlooked in the design stage or

conducted improperly by operations. If improperly conducted, corrosion can occur due to dew-point corrosion or due to process fluids left in the equipment. Inert gas blanketing may be needed to reduce these types of corrosion problems. Problems with the cleaning of process equipment generally occur during downtimes.

Seasonal Temperature Changes

Ambient temperature is an important variable that can vary widely. Metal parts exposed to the sun may reach 60 °C (140 °F) in the summer. During the winter, colder cooling water can cause a lower process exit temperature than desired. To correct this problem, plant operators will frequently decrease the water flow. All too often, the water flow is throttled at the water inlet. This can result in a fluctuating liquid level, with buildup of solids, pitting, and/or stress-corrosion cracking.

Variable Process Flow Rates

Plants are frequently operated at flow rates other than design capacity. They may be turned

down to considerably less than capacity or pushed above it. Either condition can cause corrosion problems.

Impurities

A principal cause of unexpected corrosion failures is the presence of small amounts of impurities in the chemical environment. A number of common impurities affecting corrosion are presented in Table 1.

Corrosion under Insulation

Hira S. Ahluwalia, Material Selection Resources, Inc.

CORROSION UNDER INSULATION (CUI) is a well-understood problem and mitigation methods are well established; however, it is pervasive and continues to cost the process industry many millions of dollars annually. In 2002, a large chemical company spent more than \$5 million dollars replacing type 304 stainless steel equipment because of chloride stress-corrosion cracking (CSCC) under insulation (Ref 1). The cost of the downtime due to the loss of production was even more significant. In another example, one petrochemical company estimates that CUI accounts for as high as 40 to 60% of the company's piping maintenance costs (Ref 2). Similar case histories are commonplace within the process industries. An effective CUI prevention strategy based on life-cycle costs can significantly reduce costs due to downtime, maintenance repair, and inspection. The corrosion of carbon steel under wet insulation is nonuniform general corrosion and/or highly localized pitting. In austenitic stainless steels, the main forms of corrosion are pitting and CSCC.

Corrosion of Steel under Insulation

The corrosion of carbon steel under wet insulation is nonuniform general corrosion and/or highly localized pitting. Figure 1 shows a section of a large carbon steel storage tank that has undergone corrosion in a localized region leading to a through wall hole. The corrosion occurred on the sidewall near the tank bottom where the coating failed, exposing the carbon steel to wet corrosive conditions under the insulation.

The Mechanism

Carbon steel does not corrode simply because it is covered with insulation, but because it is contacted by aerated water. The primary role of insulation in corrosion is to provide an annular space or crevice for the retention of water with full access to oxygen (air) and other corrosive media. In addition, the insulation provides a material that may wick or absorb and may contribute contaminants that increase or accelerate

the corrosion rate. The corrosion rate of carbon steel is principally controlled by the temperature of the steel surface, availability of oxygen and water, and the presence of corrosive contaminant species in the water.

Water Sources. There are two primary water sources involved in CUI of carbon steel. First, breaks in the weatherproofing can lead to infiltration of water to the metal surface from external sources such as rainfall, drift from cooling towers, condensate falling from cold service equipment, steam discharge, process liquid spillage, spray from fire sprinklers, deluge systems, washrooms, and from condensation on cold surfaces after vapor barrier damage. Second, a major corrosion problem develops in situations where there are cycling temperatures that vary from below the dew point to above ambient temperatures. In this case, the classic wet/dry cycle occurs when the cold metal

develops water condensation that is then baked off during the hot/dry cycle. The transition from cold/wet to hot/dry includes an interim period of damp/warm conditions with attendant high corrosion rates.

Contaminants. Chlorides and sulfates are the principal contaminants found under insulation. These may be leached from the insulation materials or from external waterborne or airborne sources. Chlorides and sulfates are particularly detrimental because their respective metal salts are highly soluble in water, and these aqueous solutions have high electrical conductivity. Furthermore, hydrolysis of the metal salts can create acidic conditions leading to localized corrosion.

Temperature. It is generally accepted that carbon steel operating in the temperature range of -4 to 150°C (25 to 300°F) is at the greatest risk from CUI. Equipment that operates

Fig. 1 Through wall corrosion under insulation of a large coated carbon steel storage tank. Through hole at arrow. Courtesy of Paul Powers, GE Inspection

continuously below -4°C (25°F) usually remains free of corrosion. Corrosion of equipment above 150°C (300°F), above the boiling point of water, is reduced because the carbon steel surface remains essentially dry. Corrosion tends to occur at those points of water entry into the insulation system where the temperature is below 150°C (300°F) and when the equipment is idle.

Figure 2 shows the corrosiveness of water versus temperature. The problem of steel corrosion under insulation can be classified as equivalent to corrosion in a closed hot-water system. In an open system, the oxygen content decreases with increasing temperature to the point where corrosion decreases even though the temperature continues to increase (Ref 4). In a closed system, the corrosion rate of carbon steel in water continues to increase as the water temperature increases. Estimated corrosion rate data of carbon steel under insulation plotted in Fig. 2 that were obtained from actual plant case histories confirm that the rate increases with temperature in a manner similar to that of a closed system (Ref 3). It is inferred that the same oxygen cell corrosion mechanism is taking place as in a closed system. The corrosion rates from

Fig. 2 Effect of temperature on corrosion of steel in water. Data points are from plant measurements of corrosion under insulation (Ref 3). Closed system, oxygen held in system; open system, oxygen free to escape (Ref 4)

field measurements are shown to be greater than laboratory tests, due to the presence of salts in the field. Salts increase the conductivity of the water film and thereby influence the corrosion rate.

Insulation. Corrosion under insulation of carbon steel is possible under all types of insulation. The rate of corrosion may vary depending on the characteristics of the insulation material. Some insulation materials contain water-leachable salts that may contribute to corrosion, and some foams may contain residual compounds that react with water to form an acidic environment. The water retention, permeability, and wettability properties of the insulation material also influence the corrosion of carbon steel.

Corrosion of Stainless Steel under Insulation

Corrosion under insulation in austenitic stainless steel is manifested by chloride-induced stress-corrosion cracking (CISCC), commonly referred to as external stress-corrosion cracking (ESCC), because the source of chlorides is external to the process environment. Figure 3 shows ESCC of a 100 mm (4 in.) type 304 stainless steel pipe that operated in the 50 to 100°C (120 to 212°F) range. Figure 4 shows the typical transgranular lightning strike appearance of ESCC in the pipe. External SCC of austenitic stainless steel is possible when the equipment is contacted by aerated water, and chlorides or contaminants are present in the temperature range 50 to 150°C (120 to 300°F) in the presence of tensile stresses.

The Mechanism

A detailed discussion on the mechanism of SCC can be found in a number of publications (Ref 5, 6). The mode of cracking is normally transgranular. It is well established that the

propensity for ESCC is greatest when the following conditions are present:

- A susceptible 300 series austenitic stainless steel
- The presence of residual or applied surface tensile stresses
- The presence of chlorides, bromide (Br^-), and fluoride (F^-) ions may also be involved
- Metal temperature in the range 50 to 150°C (120 to 300°F)
- The presence of an electrolyte (water)

Alloys. The stainless steels that are commonly affected by ESCC in the chemical process industries are the 300 series stainless steels, including type 304 (UNS S30400 and S30403), type 316 (UNS S31600 and S31603), type 317L (UNS S31700), type 321 (UNS S32100), and type 347 (UNS S34700). It should be noted that other stainless steels could also undergo ESCC under specific corrosive conditions.

Role of Stress. For ESCC to develop, sufficient tensile stress must be present in the material. If the tensile stress is eliminated or greatly reduced, cracking will not occur. The threshold stress required to develop cracking depends somewhat on the severity of the cracking medium. Most mill products, such as sheet, plate, pipe, and tubing, contain enough residual tensile stresses from processing to develop cracks without external stresses. When the austenitic stainless steels are cold formed and welded, additional stresses are imposed. The incidence of ESCC is greater in process piping because of the high hoop stresses normally present in piping systems. As the total stress increases, the potential for ESCC increases.

Chlorides. The Cl^- ion is damaging to the passive protective layer on 18–8 stainless steels. Once the passive layer is penetrated, localized corrosion cells become active. Under the proper set of circumstances, SCC can lead to failure in only a few days or weeks. Sodium chloride, because of its high solubility and widespread presence, is the most common corrosive species (Ref 5). This neutral salt is the most common, but

Fig. 3 External stress-corrosion cracking of a type 304 stainless steel, 100 mm (4 in.) schedule 40 pipe. The piping system was insulated with calcium silicate insulation and operated at temperatures between 50 and 100°C (120 and 212°F).

Fig. 4 Cross section through type 304 stainless steel pipe showing transgranular external stress-corrosion cracking

not the most aggressive. Chloride salts of the weak bases and light metals, such as lithium chloride (LiCl), magnesium chloride (MgCl_2), and aluminum chloride (AlCl_3) can even more rapidly crack the 18–8 stainless steels under the right conditions of temperature and moisture content.

The sources of chlorides in ESCC are from insulating materials and external sources. The insulating materials include insulation, mastics, sealants, adhesives, and cements. Experience has shown that insulating materials with chloride content as little as 350 ppm can contribute to ESCC. Typically, if the insulating material is the source of leachable chlorides, failure occurs only after a few years of operation. However, external sources of chloride account for most of the ESCC failures. The sources include rain, coastal fog, wash water, fire and deluge system testing, and process leaks or spills. Other sources of chloride ions known to be aggressive include chlorine, hydrogen chloride gas, hydrochloric acid, and hydrolyzed organic chlorides. Clearly, the presence of chlorides under acidic conditions is more aggressive than neutral or basic conditions. Failures due to chlorides from external sources tend to occur after 5 or more years of service.

The concentration of chlorides necessary to initiate SCC is difficult to ascertain. Researchers have developed cracking in solutions with remarkably low levels of chlorides (<10 ppm). The situation of chlorides under insulation is unique and ultimately depends on the concentration of chlorides deposited on the external surface of the metal. Deposits near ESCC failures have been found with as little as 1000 ppm chloride. If chlorides are detected, there will probably be some localized sites of high concentration.

Temperature. The most important condition affecting chloride concentration is the temperature of the metal surface. Temperature has a dual effect; first, elevated temperatures will cause water evaporation on the metal surface, which results in chloride concentration. Second, as the temperature increases the susceptibility to initiation and propagation of ESCC increases. External SCC occurs more frequently in the range 50 to 150 °C (120 to 300 °F). Below 50 °C (120 °F), chlorides do not concentrate to levels that cause ESCC. Above 150 °C (300 F), water is not normally present on the metal surface, and failures are uncommon. Equipment that cycles through the water dew point is particularly susceptible because during each temperature cycle the chloride salts in the water concentrate on the surface.

Electrolyte. Water is the fourth necessary condition for ESCC. Since SCC involves an electrochemical reaction, it requires an electrolyte. As water penetrates the insulation system, it plays a key role at the metal surface, depending on the equipment operating conditions. Examination of the phenomenon of corrosion of steel under insulation provides a better appreciation of the widespread intrusion of water (Ref 7–9). In effect, water may be expected to enter

the metal/insulation annulus at joints or breaks in the insulation and its protective coating. The water then condenses or wets the metal surface, or if it is too hot, the water is vaporized (Ref 7).

This water vapor (steam) penetrates the entire insulation system and settles into places where it can recondense. Because the outer surface of the insulation is designed to keep water out, it also serves to keep water in. The thermal insulation does not have to be in poor condition or constantly water soaked. A common practice in chemical plants is to turn on the fire protection water systems on a regular basis. This deluges the equipment with water. Some seacoast locations use seawater for the fire protection water. Hot food-processing equipment is regularly washed with tap water, which contains chlorides. All insulation system water barriers eventually develop defects. As the vessel/insulation system breathes, moist air contacts the metal surface. From the insulation standpoint, the outer covering acts as a weather barrier to protect the physical integrity of the insulation material. The outer coverings are not intended, nor can they be expected, to maintain an airtight and watertight system.

Prevention of CUI

Design of Insulation System. When designing an insulation system the goal is

to prevent ingress of moisture. Poorly designed or applied insulation and protrusions through thermal insulation permit water to bypass the insulation, thereby corroding the substrate material. References 10 and 11 provide detailed information on the mechanical design of insulation systems. In the author's experience, attachments to vessels and piping stems are common locations that allow water to bypass the insulation and to concentrate at the attachment point. Examples of such attachments are shown in Fig. 5 and 6. Attention to details such as these is important in order to produce a high-quality insulation system. Although the design of the insulation systems is important, prevention methodologies based on design alone are not advisable or practical in a chemical plant.

The physical characteristics of thermal insulation materials can vary widely. Some insulation materials contain a leachable inhibitor to neutralize the pH of the water in contact with the metal surface. The degree of water absorbency can also vary. For some systems, the coefficient of thermal expansion will influence the system design. For example, cellular glass insulation expands about the same as carbon steel, whereas cellular foam expands nine times more than carbon steel and therefore require expansion joints. General industry experience over the last 20 years indicates that corrosion is possible under all types of insulation. The common types of insulation materials and their recommended service temperatures are listed in Table 1.

Fig. 5 Typical vessel attachments where water may bypass insulation. Source: Ref 11

Selecting and specifying the correct insulation material can reduce corrosion of both carbon steel and stainless steels.

Organic Coating System. The application of organic coatings on both carbon steel and stainless steel equipment beneath insulation is an effective method of having a physical barrier to the corrosive electrolytes and thereby prevent corrosion. This method is effective only if a holiday-free coated surface is obtained. In the chemical plant environment, the average life cycle of a coating system is 5 to 13 years (Ref 12). In some cases when a correctly selected and correctly applied coating system is used, a 20 year service life can be achieved. Some of the parameters that need to be considered when selecting a coating system include: coating

selection, surface preparation requirements, environmental requirements, compatibility with insulating material, coating tests, coating vendor selection, specifications, inspection, and selection of coating applicator.

Coating systems that have been shown to have been used successfully in the process industries include liquid-applied coatings such as epoxies, urethanes, and polyurethanes; fusion-bonded coatings; brushable coal tar or asphalt-base coatings; mineralization coatings; and tapes. More information on the selection of protective coating is available from coating manufacturers' literature and in Ref 10. Information pertaining to organic coatings can also be found in "Organic Coatings and Linings," Vol 13A, of the *ASM Handbook*.

Fig. 6 Attachment to piping where water may bypass insulation. Attachment relies on caulking compound only. Source: Ref 11

Table 1 Typical service temperatures for thermal insulation materials

Thermal insulation material	Recommended service temperature	
	°C	°F
Polystyrene foam	-73 to +60	-99 to +140
Polyurethane foam—rigid	-73 to +82	-99 to +180
Polyisocyanurate foam—rigid	-73 to +120(a)	-99 to +248(a)
Flexible foamed elastomer	-40 to +104	-40 to +219
Cellular glass	-240 to +121	-400 to +250
Glass fiber	27 to 343	81 to 649
Mineral wool	27 to 982	81 to 1800
Calcium silicate	27 to 649	81 to 1200
Pearlite-silicate	27 to 593	81 to 1099

(a) Although some manufacturer's literature shows upper temperature limits approaching 149 °C (300 °F), experience indicates that polyisocyanurate foam begins to degrade at about 93 °C (199 °F) in the presence of moisture. A suggested practical upper limit is 66 °C (151 °F).

Personnel Protection Cages. In many instances thermal insulation is used for personnel protection from hot surfaces. The unnecessary use of thermal insulation creates a location for potential corrosion. In these cases wire "stand-off" cages should be used instead. These cages are simple in design, low in cost, and eliminate the concerns with CUI.

Thermal Spray Aluminum (TSA). For services too severe for organic coatings, such as temperature cycling above and below 150 °C (300 °F), TSA provides the best choice for corrosion protection beneath insulation. The TSA protects equipment by acting as a barrier coating and serves as a sacrificial anode protecting the substrate at the sites of any chips or breaks in the coating. The U.S. Navy has demonstrated that the use of TSA has resulted in substantial reduction in cost of its corrosion-control effort aboard its ships (Ref 13). A large petrochemical company has increased the use of TSA in its plant and has shown that large savings can be obtained based on life-cycle cost (Ref 12). Over a 20 year cost analysis, the replacement of an existing carbon steel pipe with TSA-coated carbon steel pipe compared with replacement with painted carbon steel that needs to be painted at least once during this period was shown to result in a savings of more than 100% (Ref 12). The development of more mobile thermal spray equipment with high deposition efficiency is likely to increase the use of TSA in the chemical process industry.

Aluminum Foil Wrapping of Stainless Steel Pipe. This technique is widely used in Europe by end users and engineering companies, but has not been widely accepted in North America. Aluminum foil wrapping has been used successfully for more than 30 years in preventing ESCC by chemical companies in Europe. The aluminum foil provides electrochemical protection by preferentially undergoing corrosion and maintaining a safe potential for stainless steel. The system relies on good weatherproofing and the prevention of immersion conditions. The system can be applied by the insulation contractor and, furthermore, it takes less time to apply than a coating and has minimum substrate preparation.

Wrapping pipe with 46 standard wire gage (SWG) 0.1 mm (0.004 in.) aluminum foil can prevent CISC of stainless steel pipe operating continuously between 60 and 500 °C (140 and 930 °F). The pipe should be wrapped with 50 mm (2 in.) overlap, formed to shed water on the vertical line, and held with aluminum or stainless wire. The foil should be molded around flanges and fittings. Steam-traced lines should be double wrapped, with the first layer applied directly onto the pipe, followed by the steam tracing and then more foil over the top. On vessels, the aluminum foil is applied in bands held by insulation clips and insulation support rings (Ref 14).

Use of Higher Alloyed Material. To eliminate ESCC higher nickel-, chromium-, and molybdenum-containing alloys (superaustenitic stainless steels), and the lower-nickel, higher-chromium duplex alloys can be used. These

alloys are more resistant to SCC and have been found to be resistant to ESCC under insulation. The higher cost of some of these materials makes this option unattractive. However, in some applications the lean duplex stainless steel alloys may offer a low life-cycle cost alternative.

Inspection for CUI

Inspection of insulated piping, vessels, and other components is a major challenge and can be costly and time consuming. The goal for the process industries should be to move toward an inspection-free and maintenance-free philosophy by using the appropriate corrosion-prevention methods described in the previous section with a focus on life-cycle cost.

The American Petroleum Institute code, API 570, "Inspection, Repair, Alteration, and Re-Rating of In-Service Piping Systems" (Ref 15), identifies corrosion under insulation as a special concern and requires that an appropriate amount of external visual inspection be conducted on piping systems within susceptible temperature ranges. The use of risk-based inspection (RBI) assessment conducted in accordance with API RP 580 (Ref 16) provides a methodology for prioritizing CUI-related maintenance and inspection activities. The intent of using RBI is to manage the probability of failure in piping and vessels while establishing an optimum inspection program. At the same time, a significant portion of the risk in the plant can be addressed by focusing on a relatively few items in the unit. The factors that are usually considered in a RBI analysis include: location of equipment, temperature, materials of construction, age of the equipment, the type and condition of the coating system, insulation type, and risk potential in terms of process, business, environment, and safety. Guidelines on how to conduct a visual inspection to detect signs of CUI are detailed in Ref 10 and 17.

Quantifying CUI in piping in most cases requires the removal of insulation and surface preparation prior to inspection. The cost of insulation removal, inspection, and reinstallation

can be very high. A number of nondestructive evaluation (NDE) methods that do not require removal of insulation have been developed to inspect for CUI. The Materials Technology Institute (MTI) sponsored a project to identify and evaluate the effectiveness of several NDE methods (Ref 18). The NDE methods evaluated were neutron backscatter, tangential radiography, through transmission radiography, pulsed eddy current, electromagnetic encircling coils, and three types of ultrasonic guided wave methods. The study concluded that the NDE methods could detect CUI; however, no technique is suitable for every application. The techniques vary widely in several ways such as speed, ease of inspecting piping, detectability of defects, and safety. The factors that influence the ease of inspecting piping include: pipe orientation; number of obstacles such as hangers and valve tees; proximity to the large metal masses; and insulation tie wires and jacket straps. Detectability of defects is influenced by the orientation, size, and type of defects. It should be noted that the CUI pattern may be nonuniform and spot nondestructive evaluation may be misleading.

Corrosion by Sulfuric Acid

S.K. Brubaker, E.I. Du Pont de Nemours & Company, Inc.

SULFURIC ACID PRODUCTION AND ITS USE is critical to modern industry. Its use plays some part in the production of nearly all manufactured goods. More of this acid is used each year than any other manufactured chemical.

Today, most sulfuric acid is made by the contact process, in which elemental sulfur or sulfur-containing waste is burned to form sulfur dioxide (SO_2). Sulfur dioxide is converted to sulfur trioxide (SO_3) by contact with a vanadium catalyst. The SO_3 is absorbed in oleum (fuming H_2SO_4) or H_2SO_4 in a series of towers.

The basic materials of construction for the production and handling of concentrated sulfuric acid during the early 1900s were lead, steel, cast iron, and brick. In the mid-1900s stainless steels and the "20" type alloys came into use. During the later 1900s, super stainless steels, high-nickel alloys, and fluoropolymers were developed and found to be useful for higher-temperature acid handling and processing.

The corrosiveness of H_2SO_4 depends on many factors, particularly temperature and concentration. Strong, hot conditions present the greatest problems, and few materials except platinum, tantalum, fluorocarbon plastics, and brick-lined steel will resist 60 to 98% H_2SO_4 at 120 °C (250 °F). Other variables also influence the resistance of materials to H_2SO_4 . The presence of oxidizing or reducing contaminants, velocity effects, solids in suspension, and galvanic effects can alter the serviceability of a particular material of construction.

It is unwise to select materials of construction for equipment that will handle H_2SO_4 solely on the basis of published corrosion data unless the conditions are adequately and specifically covered by the reference data or plant experience. The corrosion of metals in H_2SO_4 is complex, and an understanding of electrochemical theory is useful (Ref 1-3). Seemingly minor differences in impurities, velocity, or concentration may significantly impact service corrosion rates. Impurities such as halides generally increase corrosion. Aeration or the presence of oxidizing agents generally accelerates corrosion of non-ferrous metals and reduces corrosion of stainless alloys, but the extent of these effects depends on specific conditions.

It is advisable, therefore, to consider all general corrosion data only as an indicator of relative resistance and as a guide for further review. Final

selection of materials for specific equipment depends, of course, on such factors as allowable corrosion rate, desired mechanical and physical properties, fabrication requirements, availability, and cost (Ref 4).

Carbon Steel

General Resistance. Steel has been used for more than 100 years for handling concentrated H_2SO_4 at ambient temperatures under static and low-velocity conditions (<0.9 m/s, or 3 ft/s). A soft sulfate film forms that is highly protective unless physically disturbed. The actual corrosion rate of steel depends on temperature, acid concentration, iron content, and flow, because these parameters determine the dissolution rate of the protective sulfate film. Figure 1 shows the corrosion resistance of steel as a function of temperature for nonflowing conditions at concentrations above 65%. In the concentration range of 65 to 100%, steel is applicable for ambient-temperatures storage tanks and piping at low velocities. However, the corrosion rate of carbon steel may be excessive in the 80 to 90% acid concentration range for general applications. Within the 100 to 101% range, steel exhibits potentially high corrosion rates as the temperature exceeds 25 °C (75 °F) and is not recommended, except where low temperatures and velocities can be ensured. Steel is used in oleum service above 101% acid concentration at ambient and moderate temperatures.

Localized attack can occur even at flow velocities within the prescribed limits. Discontinuities such as short-radius elbows, excessive

Fig. 1 Corrosion of steel by H_2SO_4 as a function of temperature and acid concentration. Source: Ref 3

penetration of welds, and pipe mismatch may cause sufficient downstream turbulence to disturb the protective sulfate film, resulting in high corrosion rates. Weldments must be thoroughly inspected to ensure that they contain no slag, surface porosity, laps, excessive penetration, or other welding defects that might encourage accelerated corrosion. In addition, steel vessels and piping should be free of mill scale, or non-uniform corrosion may occur.

Hydrogen grooving is another form of localized attack that occurs on vertical or inclined surfaces exposed to the liquid phase. During the corrosion of steel by H_2SO_4 , hydrogen is evolved. If produced in sufficient quantities, the hydrogen forms small bubbles that stream along preferred paths on vertical and inclined surfaces, disrupting the soft protective iron sulfate film. Channels and deep grooves may eventually form. Grooving is commonly observed in the tops of horizontal manways on the side of vertical storage tanks and on the top 180° of horizontal pipe runs (Fig. 2). In piping, stagnant conditions promote grooving; therefore, a minimum velocity of 0.3 m/s (1 ft/s) is often recommended.

Grooving, combined with erosion-corrosion, also occurs on the sidewalls of tanks (Fig. 3). Location of the liquid inlet in the roof near the shell has, in at least two cases, resulted in combined erosion-corrosion and hydrogen grooving, which caused catastrophic rupture of large storage tanks (Ref 5).

Fig. 2 Hydrogen grooving of a 75 mm (3 in.) diam steel elbow. The elbow was sectioned; the top half is shown.

Influence of Copper. The addition of copper to steels for improved resistance to H_2SO_4 has been studied with varied results (Ref 6, 7). It is generally believed that the advantages, if any, of the use of copper-bearing steels for handling strong H_2SO_4 are not sufficient to warrant the additional expense.

Anodic protection has been used to lower corrosion rates on steel tanks storing 93 to 99% H_2SO_4 . The intent is to prolong tank life and minimize iron pickup. Typically, corrosion rates can be lowered by up to 80%. In this process, the steel is electrochemically driven from the active to the passive region by an applied potential between a cathode and the steel. If proper passivity is achieved, the corrosion rate decreases to less than 0.1 mm/yr (4 mils/yr) (Ref 8). The use of stainless steel and alloy 20Cb-3 in tanks being protected must be carefully analyzed because the passive protection potential for steel may overlap active regions for these alloys. With improvements in the H_2SO_4 production process, acid with lower iron content is being produced. This acid is more corrosive to steel than the high-iron acid. Thus, the use of anodic protection has become increasingly important.

Mechanism of Corrosion Protection. Steel corrodes in the active state at all concentrations up to 100% H_2SO_4 . At concentrations below 60 to 65%, the iron sulfate corrosion product readily goes into solution, and corrosion rates are high. At higher concentrations, the initial corrosion rate is high, but is quickly reduced by the accumulation of iron sulfate corrosion product on the surface. It has been shown that the dissolution and diffusion of ferrous sulfate from the surface is the rate-limiting step (Ref 9). The effects of velocity, concentration, and temperature on the corrosion process in piping and storage tanks have been modeled (Ref 10, 11). At concentrations from 65 to 100% at ambient temperatures, the sulfate layer diffuses into solution sufficiently slowly for the use of steel as a material of construction. Corrosion rates are typically 0.15 to 1.0 mm/yr (6 to 40 mils/yr). In the oleum range above 101% H_2SO_4 concentration (4% free SO_3), steel corrodes in the passive region because of the oxidizing effect of SO_3 . Corrosion rates are typically <0.1 mm/yr (<4 mils/yr) at ambient temperature. In the 100 to 101% concentration range, the steel goes through an active-passive transition state, and measured corrosion rates are erratic and excessive above 25 °C (75 °F).

Cast Irons

Gray cast iron has been used for piping and coolers for H_2SO_4 since acid plants were first built. Due to the brittle nature of gray cast iron and the availability of alternate materials, it has fallen out of favor over the last 20 years. Gray cast iron is more resistant to corrosion than steel in the 65 to 100% acid concentration range at ambient temperature. The higher carbon and silicon content of cast irons leads to conditions

favoring superior resistance at higher velocities and elevated temperatures, at least in the concentration range of 90 to 100%. Gray cast iron is less sensitive to velocity than steel and is frequently used up to 1.7 m/s (6 ft/s) in larger-diameter piping. The superior resistance of cast iron may be due to interference of the graphite flake network with the reaction between the acid and the metallic matrix (Ref 12). Graphite flakes may act as cathodic areas and shift the corrosion potential to a more favorable region (Ref 13).

Gray cast iron normally should not be used in the oleum range because of a tendency toward cracking. Free SO_3 is thought to attack the graphite flakes. Corrosion products form in the voids and strain the structure by volumetric expansion. Cracking of gray cast iron has also occurred in concentrated H_2SO_4 service, in which the cast iron was attached to stainless steel coolers protected by anodic protection. It is theorized that the anodic current causes the cast iron to behave as though it is in oleum service. This problem has been solved by placing 3 m (10 ft) of ductile iron piping between the cooler and the gray cast iron pipe. Ductile cast iron is not subject to the same phenomena as gray cast iron, because the graphite is in the form of isolated nodules and the metal matrix is substantially stronger.

Gray cast iron is brittle and can rupture without warning. Care must be taken to support cast iron pipe properly and to replace it before it thins excessively because of corrosion. For replacement or new piping, ductile cast iron, stainless steels with or without anodic protection, and plastic-lined pipe are now favored.

Ductile cast iron performs nearly as well as gray cast iron in concentrated H_2SO_4 at ambient temperatures. At moderate to higher temperatures, gray cast iron has lower corrosion rates, but ductile iron is often used as it is less brittle. Laboratory testing comparing the materials has been inconclusive, probably because chemical compositions of the iron vary considerably. Actual plant experiences with piping tend to indicate up to 50% higher corrosion rates for ductile cast iron versus gray cast iron, but this can be compensated for by the use of additional corrosion allowance. Ductile iron clearly has lower temperature limits than gray cast iron, and its use at higher temperatures needs to be carefully monitored.

Fig. 3 Hydrogen grooving on the sidewall of an H_2SO_4 storage tank

A modified ductile cast iron, with the trade name of "MONDI," was introduced in the 1980s and reportedly has better corrosion resistance than conventional ductile cast iron. This alloy has about 3.5% Si versus the 1.8 to 2.8% for standard ductile iron. This ductile iron has been used at 65 to 70 °C (150 to 160 °F) in 93% acid and 110 to 120 °C (230 to 250 °F) in 98 to 99% acid.

High-Silicon Cast Iron. Another material that has long been used for handling H_2SO_4 is high-silicon iron. Iron with 14.5% Si has exceptional resistance to H_2SO_4 in all concentrations to 100% up to the atmospheric boiling points. Corrosion rates are normally less than 0.12 mm/yr (5 mils/yr), as shown in Fig. 4 (Ref 14).

The corrosion resistance of high-silicon iron is due to the formation of a strong silicon-rich abrasion-resistant film. Even the most severely abrasive slurries can be handled. High-silicon irons are rapidly attacked in oleum or other services containing free SO_3 . Only SO_3 , SO_2 , and fluorine/fluoride contaminants are known to drastically alter the corrosion resistance of high-silicon iron to H_2SO_4 . The high-silicon irons are available only in the cast form. In addition, they have low tensile strength and virtually no ductility. High-silicon irons are susceptible to thermal and mechanical shock failures.

Austenitic Stainless Steels

The resistance of austenitic stainless steels to H_2SO_4 is complex due to the active-passive nature of the alloys. An excellent summary that includes corrosion rate data is provided elsewhere (Ref 15).

Mechanism of Protection. Stainless steels depend on electrochemical passivity for resistance to corrosion in H_2SO_4 solutions. Stable passivity is achieved at ambient temperatures in the very low and very high acid concentrations and in oleum.

Corrosion Resistance. At ambient temperatures, austenitic stainless steels, for example, type 304 and 316, exhibit stable passivity in H_2SO_4 above 93% concentration and are frequently used for piping and tankage where product purity is desirable. The corrosion rates are essentially nil. Molybdenum stretches the

passive region, making type 316 and 317 acceptable for service in 90 to 93% H_2SO_4 at ambient temperature. Type 316 is the preferred choice for ambient temperature 93% service as type 304 may be active-passive at slightly lower concentrations. The upper temperature limit for stable passivity for types 304 and 316 in 93% H_2SO_4 is believed to be around 40 °C (105 °F). For 98.5% H_2SO_4 , the upper stable passive limit is believed to be above 70 °C (160 °F) (Ref 16). As concentration increases above 99%, corrosivity decreases rapidly, allowing the use of stainless steels above 100 °C (212 °F).

In dilute acid, the molybdenum grades, such as type 316 and 317, are useful, although type 304 may be used when only a trace of acid is present. Figure 5 shows corrosion data for these alloys in as-mixed and refluxed (aerated) H_2SO_4 solutions (Ref 17). Stainless steels have poor resistance to deaerated dilute solutions. Higher chromium is beneficial for oxidizing conditions. Type 310 stainless steel with 25% Cr and no intentionally added molybdenum is more resistant than the lower-chromium molybdenum-bearing grades when oxidizing agents are present (Ref 15).

Fig. 5 Isocorrosion diagrams for (a) type 304, (b) type 316, and (c) type 317L stainless steels in aerated H_2SO_4 up to 50% concentration. Source: Ref 17

Effect of Velocity. If a stainless steel is in solidly passive behavior, velocity appears to have little effect on corrosion rate. Laboratory tests of type 304L with velocities to 6 m/s (20 ft/s) in 93% H_2SO_4 at ambient temperature have shown passive behavior (Ref 16). However, once the alloy drops to active-passive behavior, usually because of increasing temperature, velocity has a major effect. Under abrasive conditions, cast stainless steels have shown active-passive behavior in 96% H_2SO_4 even at ambient temperatures (Ref 18).

Effect of Aeration and Oxidants. Highly aerated solutions are much more suitable for stainless steels than air-free ones. Similarly, the presence of oxidizing impurities stabilizes the passive film, and the resistance to H_2SO_4 of austenitic stainless steels improves markedly. Cations that are easily reducible, such as Fe^{3+} , Cu^{2+} , stannic (Sn^{4+}), and ceric (Ce^{4+}) ions, are oxidizing agents that can inhibit the attack of stainless steels in H_2SO_4 solutions. It was found that 0.19 g/L of Fe^{3+} ion was sufficient to cause passivity and low corrosion rates in boiling 10% H_2SO_4 , but 0.115 g/L did not give inhibition (Ref 19).

Other oxidizing agents, such as chromic acid (H_2CrO_4) and nitric acid (HNO_3), were shown to be effective in reducing corrosion rates (Ref 20). Nitric acid concentrations as low as 1.5% mixed into H_2SO_4 were found to inhibit the corrosion of stainless steel over a wide range of H_2SO_4 concentrations at ambient and elevated temperatures (Ref 21). Oxidants in sufficient quantities were shown to reduce the corrosivity of H_2SO_4 on stainless steel by shifting the corrosion potential from an active to a passive state (Ref 22).

Effect of High Concentration and SO_3 . In strong H_2SO_4 (above 98% concentration) and in oleum, the oxidizing power of the acid increases dramatically and corrosion rates are reduced (Ref 23, 24). Figure 6 shows an isocorrosion

Fig. 6 Isocorrosion diagram of type 304L stainless steel in highly concentrated H_2SO_4 . Source: Ref 24

diagram generated for type 304L stainless steel in an absorption tower environment. Most stainless steels and nickel-base alloys have similar reductions in corrosion rates with increasing concentration. However, the higher molybdenum-containing alloys, such as alloys B-2, C-276, 904L, and 20Cb-3, are distinctly inferior (Table 1).
